

Capital Regulation and Banks' Financial Decisions*

This paper develops a stochastic dynamic model to examine the impact of capital regulation on banks' financial decisions. In equilibrium, lending decisions, capital buffer, and the probability of bank failure are endogenously determined. Compared to a flat-rate capital rule, a risk-sensitive capital standard causes the capital requirement to be much higher for small (and riskier) banks and much lower for large (and less risky) banks. Nevertheless, changes in actual capital holdings are less pronounced due to the offsetting effect of capital buffers. Moreover, the nonbinding capital constraint in equilibrium implies that banks adopt an active portfolio strategy, and hence the countercyclical movement of risk-based capital requirements does not necessarily lead to a reinforcement of the credit cycle. In fact, the results from the calibrated model show that the impact on cyclical lending behavior differs substantially across banks. Lastly, the analysis suggests that the adoption of a more risk-sensitive capital regime can be welfare improving from a regulator's perspective, in that it causes less distortion in loan decisions and achieves a better balance between safety and efficiency.

1. Introduction

Banking is one of the most regulated industries in the world. Among various regulatory measures, the regulation of bank capital is crucial due to the important role it plays in banks' soundness and risk-taking behavior, and its influence on the competitiveness of banks.¹ In practice, a key aspect of capital regulation is the calculation of minimum regulatory capital, which is typically based on the credit risk of bank assets.

A unified regulatory capital framework, which applied to all internationally active banks, was first introduced in 1988 by the Basel Committee on Banking Supervision (BCBS). It was commonly known as Basel I (BCBS 1988). However, the risk matrix was very simple in the sense that the risk weights were practically the same for bank loans of different risk.² The low sensitivity arguably could have led to severe market distortions as banks swapped low-risk assets against high-risk ones with more favorable risk weighting (regulatory arbitrage). Reflecting this, in June 2004, the Basel Committee on Banking Supervision released a revision of the existing accord on capital regulation, known as Basel II (BCBS 2006). One of the most remarkable changes under the new framework was the introduction of a more risk-sensitive capital standard.

The transition toward a more risk-sensitive capital regime has generated the discussion on its implications for the banking industry. Two major concerns arise. First, it tends to cause substantial changes in the level of bank capital. The study of Ervin and Wilde (2001), which is based on a hypothetical bank portfolio in the United States in 1990, suggests that the minimum capital requirement could drop from 8 percent to 6.8 percent with the introduction of the risk-based capital rule. Similarly, a study conducted by U.S. federal regulators (OCC, FRB, FDIC, and OTS 2004) shows that the new capital rule will cause the minimum required risk-based capital (MRC), the sum of expected and unexpected losses,

¹See Berger, Herring, and Szegö (1995) and Santos (2001) for surveys on the motivations behind capital regulation.

²Generally, G-10 government debt is weighted 0 percent, G-10 bank debt is weighted 20 percent, and other debts, including corporate debt and the debt of non-G-10 governments, are weighted 100 percent. As an exception, mortgage on residential property receives a risk weight of 50 percent.

to drop on average by 12.5 percent. Across entities, the changes in MRC vary substantially within a range of -50 percent to 70 percent, with a median reduction of 24 percent. These results raise concerns that the introduction of the new capital standard may cause abrupt and undesirable changes to the banking industry. Second, the greater risk sensitivity in the new capital regime may cause additional volatility in economic activity, sometimes cited as the procyclicality problem.³ In particular, capital requirements can increase as the economy falls into recession and fall as the economy enters an expansion. The increase in capital requirements during the downswing may result in a credit crunch and thus worsen already adverse economic conditions. The empirical relevance of this concern was later confirmed in several countries, including the United States (Catarineu-Rabell, Jackson, and Tsomocos 2005; Gordy and Howells 2006; Jordan, Pek, and Rosengren 2003; Kashyap and Stein 2004), Spain (Corcostegui et al. 2002), and Mexico (Segoviano and Lowe 2002).

However, there are several major caveats in these studies, which suggest that the above conclusions are debatable. First, these studies focus exclusively on the change in regulatory capital. Nevertheless, in order to understand the impact of regulatory measures, it is more important to examine the change in banks' actual capital holdings.⁴ A well-known fact is that most banks tend to hold a significant amount of capital above the regulatory requirement in practice, either for efficiency reasons or because the capital cushion is established as a precaution against contingencies (adverse events or regulatory penalties; see Barrios and Blanco 2003; Elizalde and Repullo 2006). The existence of capital buffers suggests that banks' actual capital holdings may not change as remarkably as regulatory capital. Equally important, if banks hold enough capital buffer during economic downturns, the procyclicality

³See Borio, Furfine, and Lowe (2001) and Jokivuolle and Kauko (2001) for a related discussion and Allen and Saunders (2004) for a literature survey.

⁴This paper uses three distinct definitions of bank capital. *Economic capital* refers to banks' capital holdings in the absence of capital regulation, *regulatory capital* refers to the minimum capital requirements based on specific capital rules, and *actual capital* (or total capital) refers to banks' equilibrium capital holdings in an economy with capital regulation. Accordingly, *capital buffer* is defined as the difference between actual and regulatory capital.

concern tends to be mitigated. Given its importance, the cyclical behavior of bank capital buffer has been investigated by many researchers, but so far the evidence has been mixed. Estrella (2004b), Heid (2005), Koopman, Lucas, and Klaassen (2005), and Peura and Jokivuolle (2004) suggest that the existence of capital buffers can potentially mitigate the volatility in total capital. By contrast, the empirical evidence in Germany (Stolz and Wedow 2005) and Spain (Ayuso, Pérez, and Saurina 2004) shows that capital buffers are also anticyclical; therefore, it is not clear whether actual capital holdings are more volatile than regulatory capital or vice versa.⁵

Second, these studies adopt a passive portfolio assumption; e.g., banks hold the same portfolio under the two capital regimes or hold portfolios as specified by the minimum capital requirements. This is questionable, given that an important objective of the revision of capital rules is to avoid excessive risk taking that may arise under the old (less risk-sensitive) regime. Hence, it is more interesting to investigate how banks adjust their risk-taking behavior in their loan-extension process. In other words, an active portfolio strategy is more appropriate for the purpose of this study.

Moreover, some of these impact studies are based on the industry information at a particular point at time. Therefore, the results fail to recognize the dynamic aspect of regulatory implications. The dynamic perspective is crucial in the sense that the underlying credit risk of bank assets can change substantially over the business cycle. As a result, the impacts on banks' capital holdings (both regulatory and actual capital) and portfolio composition tend to be different at different phases of the business cycle.

This paper seeks to fill these gaps and provide new insights on these important issues. I propose a stochastic dynamic model in which a bank's objective is to maximize shareholder value by making loans. A larger loan book yields lower return but is associated with lower risk due to benefits from portfolio diversification. Each

⁵Cross-country studies, such as Bikker and Metzmakers (2004) and Kim and Lee (2006), find mixed results on the impact of capital regulation on the dynamics of actual capital holdings. A recent study by Repullo and Suarez (2007) suggests that capital buffer tends to be countercyclical under Basel I but is procyclical under Basel II.

bank has to choose its optimal capital structure, facing the trade-off between one-period investment gains and future franchise value. In equilibrium, the bank's leverage ratio, lending strategy, and failure probability are jointly determined. I consider three economic environments: (i) the baseline economy in which capital regulation is absent, (ii) a flat-rate capital regime in which a uniform capital-asset ratio requirement is imposed, and (iii) a risk-based capital regime in which the minimum capital requirement is determined by the credit risk of bank assets. The model is calibrated to match aspects of the U.S. economy in 1980–2002, and the equilibrium outcomes under the three economic environments are compared with each other.

The numerical results show that banks' financial decisions depend crucially on the state of the business cycle, banks' initial equity holdings, and the form of capital standards. Comparing equilibrium outcomes under different capital regimes sheds new light on the issues of interest. On the one hand, the results support the view that the adoption of a risk-sensitive capital rule causes significant changes in minimum capital requirements, and the impact is substantially different across banks, depending on the risk profile of their loan portfolios. However, they also suggest that changes in actual capital holdings can be much smaller than changes in minimum capital requirements due to the offsetting effect of capital buffers. On the other hand, the results find little support for the idea that capital regulation amplifies procyclicality in bank lending. The volatility of bank credit (and economic output) over the business cycle is smaller under both capital regimes than the volatility under the baseline economy (without capital regulation). Even when comparing the two capital regimes, higher volatility of capital requirements under the risk-based capital rule does not necessarily lead to amplified swings in banks' lending activity, because the non-binding capital constraint implies that the loan portfolios chosen by banks in equilibrium are often different from those implied by regulatory capital constraints. In fact, for smaller banks, the swing in bank lending is less pronounced under the risk-based capital rule than under the flat-rate capital regime.

The model also provides a framework to compare the optimality of the two capital regimes from a regulator's perspective, assuming that the regulator has to choose between maximizing franchise value and minimizing the negative externality caused by bank failures.

Illustrative examples suggest that the risk-based capital rule can outperform the flat-rate capital requirement, in that expected franchise value is higher for the same level of bank safety. The results hold both at the micro level (comparison based on individual banks) and at the macro level (comparison based on the banking system as a whole). The intuition behind this observation is that under the flat-rate capital requirement, the failure to reward sound investments causes a big distortion in limiting the scale of lending for those banks that have access to high-return, low-risk investment opportunities. From a dynamic perspective, such distortion implies that banks have to make a large sacrifice of future franchise value in order to reduce the default risk in the current period. By contrast, the future franchise value at risk is much smaller under the risk-based capital regulation because banks can invest in high-return, low-risk projects without incurring the high cost of holding capital.

The remainder of the paper is organized as follows. Section 2 outlines the model setup and section 3 discusses the qualitative results. In section 4, the model is then calibrated to the U.S. economy, allowing us to examine the equilibrium financial decisions under different capital regimes. Section 5 compares the two capital regimes from a regulator's perspective. The final section concludes.

2. The Model

The benchmark model follows a modified version of the model developed by Cooley and Quadrini (2001) for a generic firm. I treat a bank as a special type of firm, whose objective is to maximize the expected discounted value of dividends, $E_0\{\sum_{t=0}^{\infty} \beta^t d_t\}$, where d_t is the dividend payment at time t , β is the discount factor of bank shareholders, and E is the expectations operator. Accordingly, the assumptions on the asset and liability of the *firm's* balance sheet will be modified to reflect distinctive features of the banking sector. The modified framework bears considerable similarity to the one developed by Van den Heuvel (2002).

2.1 Loans

In each period, the bank tries to maximize shareholder value by making loans. To maintain analytical tractability, this model abstracts

from the determination of lending rates by working directly with a return function of $Y_t = (z_t + \epsilon_t + \mu_t)F(L_t)$, where Y_t is the revenue from making loans (adjusted by cost of defaults), L_t is the size of the loan portfolio, and $F(\cdot)$ satisfies $F(0) = 0$, $F' > 0$, and $F'' < 0$.⁶ The concavity of the $F(\cdot)$ function implies decreasing returns to scale for bank investments, which is standard in the literature and has been supported by empirical findings in Berger et al. (2005), Carter and McNulty (2005), and Cole, Goldbert, and White (2004), among others.

The other three variables— z_t , ϵ_t , and μ_t —jointly determine the profitability of bank lending. In particular, z_t represents the state of the economy that determines the level of investment yields and follows a first-order Markov process (assumption 1), ϵ_t is a bank-specific shock that determines the risk of bank assets (assumption 2), and μ_t measures the benefit from monitoring as it is explained below (assumption 3).

ASSUMPTION 1. The state of the economy, z , takes values in a finite set $Z = \{z_1, z_2, \dots, z_N\}$ and follows a first-order Markov process with transition probabilities $P(z_{t+1}|z_t)$.

ASSUMPTION 2. The bank-specific shock ϵ is independently and identically distributed and has a normal density function $N(0, \sigma_\epsilon^2(L))$. The volatility is inversely related to the size of bank assets, i.e., $\frac{d\sigma_\epsilon}{dL} < 0$.

At the beginning of each period, each bank observes z_t but not ϵ_t . In other words, each bank knows the level of expected investment yields in the current period and is aware that the underlying risk depends on its lending strategy. The above two assumptions suggest that when a bank chooses the size of its loan portfolio, it faces the trade-off between return and risk. A larger loan portfolio produces a lower average return but is also less risky, the latter of which can

⁶This partial-equilibrium assumption enables me to isolate the potential cyclicity coming from the supply side of the bank loan market. As a trade-off, the financing strategies of borrowers and the impact of banks' lending decisions on the real economy, which would be important in a general equilibrium setting, are ignored in this paper.

be justified on the ground of greater scope for diversification as proposed in finance theory. For instance, a report by the Group of Ten (2001) suggests that consolidation of banks within the United States has led to reductions in risk due to geographic diversification.

Finally, there exists another bank-specific term, μ , which represents the contribution of bank-specific efforts in improving investment returns. Such efforts can vary across banks due to differences in managerial skills, market power, and monitoring incentives. By paying a monitoring cost of $\theta(\mu)$ per unit of loan, the bank is able to improve the average investment return by μ .⁷ This unit cost increases in μ at a growing rate, implying that the room for return enhancement tends to become smaller, i.e., a diminishing benefit from monitoring.

ASSUMPTION 3. *The function $\theta(\mu)$ satisfies $\theta(0) = 0$, $\theta'(\cdot) > 0$, and $\theta''(\cdot) > 0$.*

The model abstracts from the determination of lending rates and assumes instead a continuous distribution of net revenues.⁸ The continuity assumption can be justified as follows. Suppose that a bank can make many individual loans, with a fixed lending rate for each loan. Since each loan can go bad with positive probability, the effective average return of the whole portfolio tends to be distributed over a large set of real numbers, with the maximum being the highest possible return if no default occurs and the minimum the worst scenario if all loans default.

2.2 Deposits and Equity

A bank begins each period with equity capital equal to e_t . The bank finances its investment by equity capital and bank deposits, the latter being a debt instrument with a fixed return of r_t^d .

Bank deposits are not risk free, in the sense that the bank may default if its loan investment does not generate enough profits.

⁷In the literature, the monitoring effort could have two effects. One is to induce entrepreneurs to choose high-productivity projects; the other is to reduce the business risk. Since the revenue function refers to default-adjusted returns, both effects tend to increase the expected revenue.

⁸The same assumption is adopted by Acharya (2003).

Therefore, a risk premium is charged to compensate for the default risk. This paper abstracts from the supply of bank deposits from the household sector by assuming that the elasticity of the deposit supply is infinite and by making the following assumption.

ASSUMPTION 4. Depositors are risk neutral, and their reservation return is the risk-free rate, r_t^f .

The assumption of perfect access to nonreservable deposits is also adopted in Van den Heuvel (2002).⁹ The advantage of this assumption is that it allows me to focus on the bank capital channel through which the change in capital regimes affects banks' lending behavior. On the other hand, it implies that the bank lending channel does not exist in this model, since a necessary condition for the existence of an effective bank lending channel—that shocks to reservable deposits should affect the bank's loan supply (Bernanke and Blinder 1988; Kashyap and Stein 1994)—is absent from this model.

However, this paper departs from the assumption in Van den Heuvel (2002) that bank deposits are fully insured (with zero premium) and, by extension, the deposit rate equals the risk-free rate.¹⁰ Instead, the bank will need to pay a risk premium in line with its likelihood of default. This is important in that a blanket deposit-insurance scheme tends to cause the moral hazard problem, which introduces undesirable bias in banks' financial decisions. Assuming that depositors are risk neutral and the expected payoff on bank deposits is $E(r)$, the supply function is

$$D_t^s = \begin{cases} 0 & \text{if } E(r) < r_t^f \\ [0, \infty] & \text{if } E(r) = r_t^f \\ \infty & \text{if } E(r) > r_t^f. \end{cases} \quad (1)$$

At the end of each period, banks receive revenues on their asset portfolios and pay back deposits. A solvent bank chooses its dividend

⁹By assuming a perfect access to deposits, this paper also abstracts from the vulnerability issue related to the bank-run phenomenon, as examined in Diamond and Dybvig (1983).

¹⁰The assumption that a risk premium is charged for bank deposits is approximately equivalent to the alternative assumption that bank deposits are fully insured by a risk-based deposit-insurance scheme.

payment (d_t) or, equivalently, its initial equity holding (e_{t+1}) for the next period. Importantly, the dividend is allowed to be negative in this model; i.e., the bank is able to issue new equity if necessary. Nevertheless, issuing new equity is costly. This is consistent with the statement made by practitioners and can be justified with respect to transaction costs and differential taxation levels for equity. Specifically, the cost of raising new equity is assumed to be linear following Cooley and Quadrini (2001).¹¹

ASSUMPTION 5. *The bank pays an issuance cost of $\Lambda(-d_t) = -\lambda d_t$ to raise new equity in the amount of $-d_t$ ($d_t < 0$).*

Finally, this model makes the following assumption on the exit of a bank.

ASSUMPTION 6. *A bank defaults if its net asset value drops below zero. A bank cannot reenter the market once it exits; i.e., its franchise value is zero thereafter.*

Here the bank's net asset value is defined as the end-of-period total revenue minus the bank's debt liability, i.e., the principal and interest payments on bank deposits. If the bank's net asset value drops below zero, its equity capital is negative and it claims bankruptcy. In other words, the renegotiation of bank debt is not allowed in this paper and a default automatically leads to permanent exit.

2.3 Capital Regulation

Regulation is introduced in the form of a minimum capital requirement imposed by the regulatory authority. Each bank has to meet this requirement at all times. The minimum level of bank capital typically depends on the size of the bank's loan book and, under a risk-based capital regime, is related to the risk profile of bank assets.

¹¹The cost of raising new equity is assumed to be constant over time. In practice, it is often more expensive for banks to raise fresh capital in economic downturns. Numerical studies show that introducing time-varying cost of equity issuance does not change the results qualitatively.

ASSUMPTION 7. *The bank has to meet the minimum capital requirement, e_{min} , which depends on the characteristics of bank assets.*

Notice that the capital regulation, combined with the equity issuance cost assumption, causes deviations from the Modigliani-Miller framework. Without these assumptions, whether bank loans are financed with deposits or equity is irrelevant. As explained later, the probability of default and the subsequent losses increase banks' willingness to hold more capital than required.

Owing to the simplified maturity structure of bank assets and liabilities in this paper, the minimum capital requirement is effectively operative only at the moment that the bank decides on the size of its loan portfolio.¹² Throughout the paper, I assume that the minimum capital requirement cannot be violated or, equivalently, that the penalty cost is infinite and the bank's franchise value goes to zero if it fails to meet the minimum capital requirement.¹³

This paper examines two alternative forms of capital requirements. The first form imposes a flat capital/asset ratio requirement (κ) of 8 percent on all banks. That is, the level of regulatory capital depends on the size of bank assets but not their riskiness. By contrast, under the alternative form, the minimum regulatory capital is calculated on the basis of the risk profile of bank assets. In particular, it is determined in a way that the probability of default for the bank does not exceed a threshold level (0.1 percent). That is, the minimum level of regulatory capital (e_{min}) is determined by¹⁴

$$(z + \epsilon_{0.001} + \mu)F(L) - \theta(\mu)L = (L - e_{min})r^d,$$

¹²Given that a bank's portfolio is fixed during each period, meeting the minimum capital requirement at the beginning of a period (when the loan is extended) implies that the requirement is not violated throughout the period. Moreover, it is not meaningful to discuss capital charges after the realization of bank-specific shocks, particularly under the risk-based capital regime, because the uncertainty in asset returns is eliminated.

¹³In a model with richer maturity structure of bank assets and liabilities, the capital requirement might be violated subject to a non-infinitely harsh penalty.

¹⁴Here the calculation is based on the credit VaR (value-at-risk) for the bank portfolio as a whole rather than on the basis of individual loans. Gordy (2003) and Kupiec (2004) prove that when the default risk is driven by a single common factor and the bank portfolio is fully diversified, the two definitions yield the same level of regulatory capital.

where $\epsilon_{0.001}$ is the 0.1 percent critical value of the normally distributed variable ϵ with mean zero and standard deviation of σ_ϵ .¹⁵ The above equation implies that if a bank holds the required level of capital, there is 0.1 percent probability that the bank's revenue will be insufficient to finance the bank's deposit liability; i.e., the bank will become insolvent. Because the default risk is very small, the deposit rate should be very close to the risk-free rate. Therefore, the above equation can be approximated by

$$e_{min} \approx -\frac{(z + \mu)F(L) - (r^f + \theta(\mu))L}{r^f} - \frac{\epsilon_{0.001}F(L)}{r^f}. \quad (2)$$

In equation (2), the minimum capital requirement consists of two components. The first component refers to the expected loss and the second to the unexpected loss of the bank's portfolio. The expected loss is jointly determined by the state of the economy and the bank's choice of monitoring effort.

2.4 Timing

At the beginning of each period, there exists a continuum of banks each with equity equal to $e_{i,t}$, which is carried over from last period. The state of the economy, z_t , is known since the end of last period, while the bank-specific shock $\epsilon_{i,t}$ is realized at the end of the current period. That is, at the moment of making lending decisions, each bank knows z_t but does not know $\epsilon_{i,t}$. Since banks' decisions are independent of each other, in the remaining part the analysis will focus on the optimization problem of an individual bank, and the subscript i , which represents bank-specific variables, will be dropped.

The bank then decides on the volume of loans it will supply (L_t) and the amount of monitoring cost it will pay (θ_t). To finance the loan portfolio, the bank's liability comprises equity holding (e_t) and deposits ($L_t - e_t$), the latter paying an equilibrium deposit rate of

¹⁵Implicitly, I assume that banks have an incentive to disclose accurate information on their capital adequacy, monitoring effort, and loan risk. Estrella (2004a) suggests that it can be achieved via the combination of voluntary disclosure, direct supervision, and financial market discipline, which is beyond the scope of this paper.

r_t^d . The bank's financial structure has to meet the regulatory capital requirement, if one exists.

At the end of each period, the bank-specific shock ϵ_t is realized and depositors are paid back. The bank either continues its operation (if its net asset value is positive) or files for bankruptcy (if its net asset value drops below zero). If a bankruptcy occurs, all depositors receive an equal amount of payment by splitting residual assets on the bank's balance sheet.

Lastly, at the end of each period, the state of the economy in the next period, z_{t+1} , is revealed. Depending on the amount of net profits and the future state of the economy, a solvent bank chooses whether to distribute dividends to its shareholders or to issue new equity (d_t). This choice is reflected on the bank's initial equity holding for the next period, e_{t+1} .

3. The Solution to the Model

The bank's problem can be solved using dynamic programming techniques and the backward-induction method. At each period, a bank makes three important decisions: choosing the size of its loan portfolio (L_t) and the monitoring effort (θ_t) at the beginning of the period and deciding on the dividend policy (d_t) at the end of the period.

I first examine the solvency condition for each bank at the end of each period. For given initial equity (e_t), bank lending (L_t), deposit rate (r_t^d), and monitoring effort (θ_t), the end-of-period net asset value of the bank is

$$\pi(L_t, \mu_t, \epsilon_t, r_t^d) = (z_t + \epsilon_t + \mu_t)F(L_t) - \theta(\mu_t)L_t - r^d(L_t - e_t). \quad (3)$$

There are two possible outcomes. If the bank's net asset value is positive—i.e., $\pi_t > 0$ —depositors receive full payment. Otherwise, the bank files for bankruptcy and depositors have to accept a smaller payment prorated by the amount of residual assets on the bank's balance sheet, which equals $(z_t + \epsilon_t + \mu_t)F(L_t) - \theta(\mu_t)L_t$.

Accordingly, the critical value of the bank-specific shock, $\bar{\epsilon}$, is defined by

$$\pi(L_t, \mu_t, \bar{\epsilon}_t, r_t^d) = 0. \quad (4)$$

For $\epsilon \geq \bar{\epsilon}$, depositors receive full payment; otherwise, the bank defaults. Since depositors are risk neutral, in equilibrium their

expected payoff should equal the return on risk-free investments (see equation (1)). That is,

$$\int_{\bar{\epsilon}_t}^{\infty} r_t^d(L_t - e_t)\phi(\epsilon)d\epsilon + \int_{-\infty}^{\bar{\epsilon}_t} [(z_t + \epsilon_t + \mu_t)F(L_t) - \theta(\mu_t)L_t]\phi(\epsilon_t)d\epsilon = r_t^f(L_t - e_t), \tag{5}$$

where $\phi(\epsilon)$ is the probability density function of the shock variable ϵ . Combining equations (4) and (5), $\bar{\epsilon}_t$ and r_t^d can be jointly determined conditional on the choice of L_t and μ_t .

$$\bar{\epsilon}_t = \bar{\epsilon}(L_t, e_t, \mu_t) \tag{6}$$

$$r_t^d = r^d(L_t, e_t, \mu_t) \tag{7}$$

LEMMA 1. $\bar{\epsilon}$ increases with bank asset (L) and decreases with bank equity (e).

Proof. Based on equations (4) and (5), it can be easily derived that

$$\frac{\partial \bar{\epsilon}}{\partial L} = \frac{1}{1 - \Phi(\bar{\epsilon})} \cdot \left\{ \frac{\theta(\mu) + r_f}{F(L)} \cdot \left(1 - \frac{F'(L)L}{F(L)} \right) + \frac{F'(L)e}{F(L)^2} \right\} > 0$$

$$\frac{\partial \bar{\epsilon}}{\partial e} = -\frac{r^f}{F(L) \cdot (1 - \Phi(\bar{\epsilon}))} < 0.$$

Lemma 1 is quite intuitive. Notice that $\bar{\epsilon}$ is the threshold value above which a bank can generate positive net profits; hence, a higher $\bar{\epsilon}$ indicates lower profitability and a higher probability of bank failure. Everything else constant, an increase in bank assets tends to lower bank profits and increase bank fragility for two reasons. For one, it lowers the marginal return of bank assets because of the concavity of the revenue function. Moreover, it increases the leverage ratio, pushes upward the default boundary ($\bar{\epsilon}$), and, consequently, raises the probability of default ($\Phi(\bar{\epsilon})$). Similarly, lower bank equity increases the probability of bank failure because of higher leverage.

Once $\bar{\epsilon}_t$ is determined, the net asset value of the bank can be rewritten as

$$\pi(L_t, \mu_t) = \begin{cases} (\epsilon_t - \bar{\epsilon}_t)F(L_t) & \text{if } \epsilon \geq \bar{\epsilon}_t \\ 0 & \text{if } \epsilon_t < \bar{\epsilon}_t. \end{cases} \tag{8}$$

Define $V(e, z)$ as the value function for a bank with an initial equity of e and the initial state of the economy z . The bank's optimization problem can be written as follows (equations (9)–(14)):

$$V(e_t, z_t) = \max_{(L_t, \mu_t)} \sum_{z_{t+1}} \int_{\bar{\epsilon}_t}^{\infty} W(\pi(L_t, \mu_t, \epsilon_t, e_t), z_{t+1}) \cdot P(z_{t+1}|z_t)\phi(\epsilon)d\epsilon \tag{9}$$

subject to equations (6), (7), (8), and

$$L_t \geq e_t \tag{10}$$

$$e_t \geq e_{min}(L) \tag{11}$$

$$W(\pi(L_t, \mu_t), z_{t+1}) = \max_{e_{t+1}} \{d(\pi_t, e_{t+1}) + \beta V(e_{t+1}, z_{t+1})\} \tag{12}$$

subject to

$$d(\pi(L_t, \mu_t), e_{t+1}) = \begin{cases} \pi(L_t, \mu_t) - e_{t+1} & \text{if } \pi_t \geq e_{t+1} > 0 \\ [\pi(L_t, \mu_t) - e_{t+1}](1 + \lambda) & \text{if } 0 \leq \pi_t < e_{t+1} \end{cases} \tag{13}$$

$$e_{t+1} = 0 \quad \text{if } \pi_t < 0. \tag{14}$$

By solving the above dynamic problem, the bank maximizes the expected value for its shareholders. The uncertainty in future franchise value comes from both the uncertainty about the future state of the economy and the riskiness of bank assets. Franchise value drops to zero when $\epsilon < \bar{\epsilon}(L_t, \mu_t)$, because in that case the bank loses all its equity capital and is forced to exit the market. Equation (11) is the regulatory capital constraint (if applicable). The bank's equity holding must be higher than the minimum requirement, which equals $\kappa \cdot L$ under the flat-rate capital requirement and is endogenously determined under the risk-based capital requirement (equation (2)). The embedded dynamic programming problem

(equations (12)–(14)) is the dividend policy to be chosen by the bank at the end of each period, which is equivalent to the choice of e_{t+1} . If the bank chooses to issue new equity, d_t is negative and the bank pays an additional cost of λ for each unit of fresh capital.

The solution to this problem has the following properties.

PROPOSITION 1. *There exists a unique function $V^*(e, z)$ that solves the dynamic programming problem (9). The optimal value function is strictly concave in e .*

Proof. See the appendix.

PROPOSITION 2. (optimal policy functions)

- (i) *The optimal monitoring effort, μ^* , is a function of L and is independent of z and ϵ . It satisfies $F(L) = \theta'(\mu^*)L$.*
- (ii) *The optimal dividend policy follows a cutoff rule; i.e., there exists a pair (π_1, π_2) with $\pi_1 \leq \pi_2$, for which the bank issues new equity ($d < 0$) if $\pi < \pi_1$, retains all profits ($d = 0$) if $\pi \in [\pi_1, \pi_2]$, and distributes dividends ($d = \pi - \pi_2$) if $\pi > \pi_2$.*

Proof. See the appendix.

Proposition 2(i) suggests that the level of monitoring effort is chosen to maximize the expected net profit in the current period and is independent of the uncertainty in asset returns and the bank's future franchise value. This is because, by assumption, the monitoring effect affects the bank's revenue as an additive component, $\mu_t F(L_t) - \theta(\mu_t)L_t$. As a result, the optimal monitoring effort that maximizes this component also generates a current-period profit outcome that strictly dominates any other solution and, by extension, maximizes the bank's franchise value. This result is very useful, as it reduces the number of free parameters by one in the value function iteration procedure and simplifies the algorithm significantly.

The strict concavity of V^* implies that the dividend policy assumes a simple form as specified in proposition 2(ii). Suppose that the feasible values of e are restricted to a set $[e_{min}, e_{max}]$. In the

embedded dynamic programming problem (13), the marginal cost of bank equity is 1 if the bank does not issue new equity or $1 + \lambda$ if the bank issues new equity. At the same time, the marginal benefit of bank equity, irrespective of whether new equity is issued or not, is downward sloping and equals $V'(e_{t+1}|z_t)$. This trade-off is illustrated in figure 1. Suppose that e^1 (or e^2) is the critical value of e_{t+1} at which the marginal benefit equals the marginal cost if new bank equity is issued (or if no new equity is issued); the bank's dividend policy must follow the cutoff rule as stated above with $\pi_1 = e^1$ and $\pi_2 = e^2$. The reason is as follows. If the bank's net asset value is smaller than e^1 , the bank has the incentive to raise new equity to the target level e^1 , because the increase in the bank's franchise value

Figure 1. The Determination of the Bank's Dividend Policy

Note: The two horizontal lines represent the marginal cost of bank equity when new equity is issued (upper line) or is not issued (lower line). The downward-sloping curve represents the marginal benefit of bank equity.

exceeds the equity issuance cost. By contrast, when $\pi > e^2$, the bank chooses to distribute dividends in the amount of $\pi - e^2$, at which point the marginal decrease in bank value equals the marginal benefit of dividend payment. When the net asset value is in the middle range, the bank prefers to reinvest all profits because it increases the shareholders' value by more than paying the profits out as dividends; nevertheless, no extra equity will be raised, because the cost is relatively too high.

Notice that the two critical values, π_1 and π_2 , change with the state of the business cycle but are independent of bank characteristics. In other words, the "optimal" range of equity holding is the same for all banks. Of course, the choice of equity holding within this range depends largely on the realization of bank-specific shocks, suggesting that the equilibrium size distribution of bank equity exhibits substantial cross-sectional differences (this issue will be reexamined later).

The optimal cutoff rule implies that when a bank chooses its lending strategy (L), it faces the following trade-offs.¹⁶ First, without considering the possibility of bank failure, banks tend to choose an optimal loan volume that maximizes their current-period expected profit. Importantly, this optimal loan volume is the same for all banks because they have the same investment opportunities.¹⁷ In this sense, initial equity size does not play a role, as all banks tend to choose the same portfolio size, which implies that smaller banks would choose higher leverage ratios. Second, the possibility that a bank may fail would affect its lending decision in an important way. As lemma 1 suggests, the probability of bank failure increases in portfolio size and decreases in banks' initial equity holdings. Therefore, in making portfolio decisions, small banks would pay more attention to expected losses in franchise value (due to bank failure) and choose a lower leverage ratio than the one driven by the efficiency concern alone (as discussed above). Lastly, the existence of equity issuance cost adds another layer of complexity to banks'

¹⁶The first-order condition is complicated, so I do not state it explicitly here.

¹⁷Based on equation (3) and proposition 2(i), expected profit in the current period equals $E(\pi|z) = zL^\alpha + \frac{L^{2\alpha-1}}{4c_0} - r^f(L - e)$. It is straightforward to show that there is a uniform L that maximizes the expected profit for all banks.

lending decisions, because the size of bank asset has an ambiguous effect on the magnitude of this cost.¹⁸ As a result, a closed-form solution is ruled out in the model. The remaining part of the paper employs numerical examples to illustrate the properties of the solution and the equilibrium relationship among bank size, leverage, profits, and the probability of failure.

4. Calibration

4.1 Parameterization

The model parameters are calibrated based on the U.S. data in 1981–2002. Table 1 summarizes the input parameters used in the numerical analysis.

- The risk-free rate is fixed at 3 percent, close to the average real risk-free rate (short-term Treasury rate adjusted by inflation) in the United States in the period 1981–2002 (which equals 3.07 percent).

Table 1. Model Parameters for the Calibration

Risk-Free Rate	r^f	1.030
Returns-to-Scale Parameter	α	0.985
Economic State	z_H	1.070
	z_L	1.052
Transition Matrix	H \rightarrow H	0.800
	L \rightarrow L	0.800
Standard Deviation of the Shock	$\sigma_\epsilon(L)$	$\frac{1.05}{L+15}$
Monitoring-Cost Parameter	c_0	6.500
Intertemporal Discount Rate	β	0.950
New-Equity Premium	λ	0.300
Minimum Capital Requirement	κ	0.080

¹⁸Based on equation (8), the two critical net asset values can be transformed into two critical values for bank-specific shocks. Specifically, a bank chooses to issue new equity when the bank-specific shock is greater than $\bar{\epsilon}$ but lower than $\epsilon_1 = \bar{\epsilon} + \frac{e^1}{F(L)}$. The change in loan volume (L) has an ambiguous effect on the probability of new equity issuance, $\Phi(\epsilon_1) - \Phi(\bar{\epsilon})$, and the expected cost of equity issuance.

- The concave return function $F(\cdot)$ is specified as $F(L) = L^\alpha$ with $\alpha = 0.985$. This returns-to-scale parameter is close to the one adopted by Cooley and Quadrini (2001). The parameter must be strictly less than one, because otherwise the optimal size of the bank goes to infinity. In addition, it is chosen close to one to avoid the large discrepancy in investment returns between large and small banks.
- The state of the economy is represented by z . For simplicity, I assume that z only takes two possible states: high (H) or low (L). The probability of staying at the same state in the next period is set to be 0.800, which implies that the same state of economy lasts for four years on average. The bank-specific shock ϵ is assumed to be normally distributed with mean zero and standard deviation σ_ϵ , which will be discussed later.

The choice of two possible states of the economy, z_H and z_L , attempts to match the loan premium observed in the data. I rank the annual loan premium (defined as loan rates minus short-term Treasury rates) during the period 1981–2002 and divide the sample into two subgroups. The average loan premium in the good eleven years is 3.88 percent and in the bad eleven years is 2.12 percent. Hence I set the two shocks as $z_H = 1.070$ and $z_L = 1.052$ (i.e., excess returns of 4 percent and 2.2 percent), respectively.

- The determination of σ , the return volatility, is not straightforward. Following conventional finance theory, I first assume a particular functional form for the relationship between the volatility and the size of bank assets: $\sigma(L) = \frac{a_1}{L+a_2}$. The two constant terms a_1 and a_2 are then chosen so that the Sharpe ratios, defined as the bank's excess return on assets (over the risk-free rate) divided by its standard deviation, are within a reasonable range in equilibrium. Rosen (2005) documents that the median Sharpe ratio for U.S. banks during the period 1977–2003 is about 0.90. For this study, $a_1 = 1.05$ and $a_2 = 15$ so that, in equilibrium, the Sharpe ratios vary between 0.40 and 1.40, with a median of 0.92.
- The cost of monitoring effort is specified as a quadratic form $\theta(\mu) = c_0\mu^2$, where $c_0 = 6.5$. I choose this particular value to offset the decreasing returns-to-scale effect due to the concavity of the return function, so that in equilibrium the

average loan premium matches the target level. Nevertheless, the monitoring-cost parameter is not crucial in this study, and varying this parameter has only a minor impact on the results.

- The intertemporal discount factor equals 0.95. This is very close to the one adopted by Cooley and Quadrini (2001) and is also consistent with the business-cycle literature.
- Following Cooley and Quadrini (2001), the cost of issuing new equity, or the new share's premium, is set to be 30 percent. The magnitude of the equity issuance cost is also in line with the size of the tax burden (40 percent) discussed in Van den Heuvel (2002), an alternative way to introduce the differentiation between equity and debt financing.
- Under the flat-rate capital requirement, the minimum capital-asset ratio equals 8 percent.

The computational procedure of the dynamic programming problem is described in the appendix. The results presented are based on the discretization using a grid with 240 points for bank equity (e), net asset value (π), and loan volume (L).

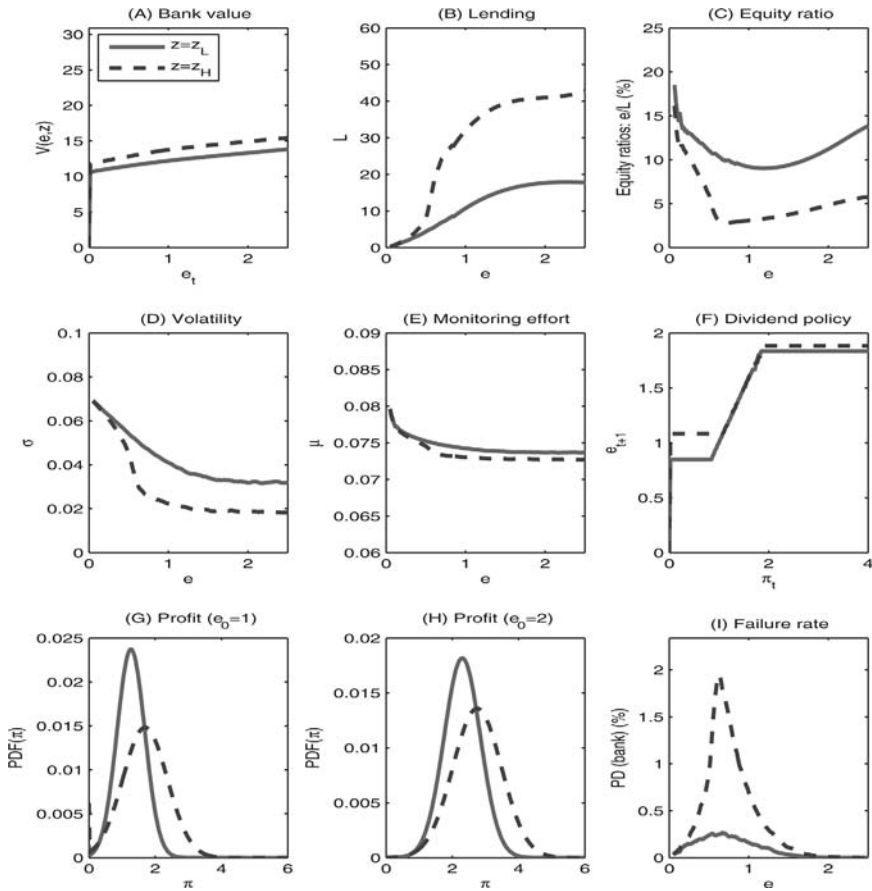

4.2 *A Baseline Model without Capital Regulation*

The baseline model examines the banks' financial decisions in the absence of regulation, i.e., when the capital requirement is zero. This provides a benchmark for judging the impact of different forms of capital regulation. The characteristics of banks' equilibrium behavior are shown in figure 2. Noticeably, the equilibrium financial decisions of banks largely depend on their initial equity holdings (hereafter referred to as "size") and the state of the business cycle.

First of all, panel A of figure 2 indicates that the bank's franchise value is higher in the good state and increases with bank size.

Second, panels B and C plot the bank's lending decisions. Generally, bank lending increases during the expansion period and falls during the downturn period. This procyclical lending behavior is a result of maximizing profits when the average return is high. The optimal leverage ratio (the inverse of equity/asset ratio) can be as high as in the range of 15–35 in the good state and as low as 6–10 in the bad state.

Figure 2. Equilibrium Outcomes under the Baseline Economy

Note: The figure plots the equilibrium outcomes under the baseline economy (without capital regulation), including banks' franchise values (V), the volume of loan portfolio (L), equity/asset ratios, asset-return volatility (σ), monitoring efforts (μ), the dividend policy, the probability distribution of end-of-period net asset values for a small bank (initial equity = 1) and a large bank ($e_0 = 2$), and the probability of bank failure. Notice that the dividend policy is equivalent to choosing the next period's equity (e_{t+1}), and all banks choose the same optimal dividend policy in equilibrium.

Moreover, the optimal leverage ratio differs across banks. As shown in the figure, large and very small banks choose low leverage in equilibrium, while mid-sized banks choose high leverage.¹⁹ This cross-sectional difference is driven by the trade-off between one-period gains (an efficiency concern) and future franchise value (a safety concern), as discussed in section 3. On the one hand, there is an optimal scale of bank lending that maximizes the expected profit of each bank in the current period due to the same lending opportunity (see footnote 17). Other things equal, each bank has the incentive to choose this optimal lending scale, implying that the optimal leverage ratio would be higher for smaller banks. On the other hand, high leverage increases the probability of bank failure and reduces the bank's value in the future. The equilibrium lending decision depends on the relative importance of these two effects. The numerical example suggests that, for very small banks, focusing solely on the efficiency leads to very high leverage and high default risk. The future franchise value cost is so high that these banks will choose a prudent lending strategy (i.e., the safety concern dominates). As bank equity increases, the stronger capital position implies that banks can maximize current-period gains without increasing the probability of default substantially. Hence the optimal leverage ratio increases to reach the balance between the marginal benefit from investment gains and the marginal cost of bank failure. However, at a certain point (when the capital position is strong enough) the efficiency aspect dominates the safety concern and the optimal leverage ratio decreases with bank size. The combined effects explain the "U-shaped" optimal equity/asset ratios as observed in the graph.

Third, panels D and E show the risk profile of bank investments and banks' monitoring efforts. Smaller banks are associated with smaller portfolio investments, which have high return but high risk as well. In order to stay in the business, smaller banks are willing to

¹⁹The optimal dividend policy, as shown in panel F, suggests that bank size is approximately between 1 and 2 for all banks. Although bank size here does not map directly into the observed data, it is reasonable in this paper to interpret banks of size 2 as the largest ones in the industry, banks of size 1 as the small and established banks, and banks of any size in between as mid-sized banks. Banks with a size smaller than 1 represent the smallest ones that are still at their infancy stage.

devote a higher monitoring effort (per unit of asset) to reducing the probability of failure. In addition, when the economic conditions are favorable, high productivity induces banks to lower their monitoring efforts because the marginal benefit of inducing higher returns through this channel is smaller.

Fourth, panel F shows the optimal dividend policy or, equivalently, the choice of next period's initial equity, which follows a cutoff rule as described in proposition 2(ii). As mentioned above, the threshold values in the cutoff rule only depend on the state of the business cycle but are independent of bank characteristics. That is, irrespective of banks' initial equity in the current period, their initial equity in the next period will be distributed within the same "optimal" range. However, the size distribution within this range is different across banks, because it depends on the realization of end-of-period net asset values. Panels G and H illustrate the probability distributions of end-of-period net asset values for two hypothetical banks—a small bank ($e_0 = 1$) and a large bank ($e_0 = 2$). Large banks are more likely to earn higher profits and remain the business leaders in the next period. This is not surprising, because strong capitalization implies that these banks can choose to maximize investment profits without worrying too much about the possibility of failure. By contrast, the growth capacity of small banks is limited due to the concern that a high-leveraged capital structure, which is desirable from the perspective of profit maximization, tends to increase the probability of bank failure substantially.

Lastly, panel I shows the probability of bank failure during the two stages of the business cycle. Overall, the predicted bank failure rates are within a reasonable range, with a peak level of 1–2 percent and a low level of 0.01–0.04 percent. This is in line with the historical observations before a mandatory capital requirement was applied in 1988.²⁰ Importantly, the failure probability differs substantially across banks. In line with the difference in bank leverage, an inverse U-shaped curve is observed across banks of different sizes. The largest and smallest banks have lower leverage, and their default probabilities are very low. By contrast, mid-range banks

²⁰Because the probability of default is very small for all banks, the difference between default-adjusted deposit rates and the risk-free rate is negligible (recall assumption 4).

engage in aggressive lending and, consequently, incur a high risk of default.

Interestingly, the probability of bank failure is much higher in the upturn of the business cycle. This supports the view that business risks build up during the expansion period.²¹ As former Federal Reserve Chairman Alan Greenspan noted, "The worst loans are made at the top of the business cycle" (Greenspan 2001). Borio, Furfine, and Lowe (2001) and Borio and Lowe (2002) document the same pattern that systemic risk tends to build up in the booming period. Notice, however, that in this paper, the higher systemic risk during upswings is not caused by underestimation of the business risk. Instead, the forward-looking banks are fully aware of the risk involved: they are willing to increase their risk exposure in the pursuit of higher returns. In other words, the one-period expected gain from risk taking exceeds the franchise value at risk.

4.3 Equilibrium Outcomes under Capital Regulation

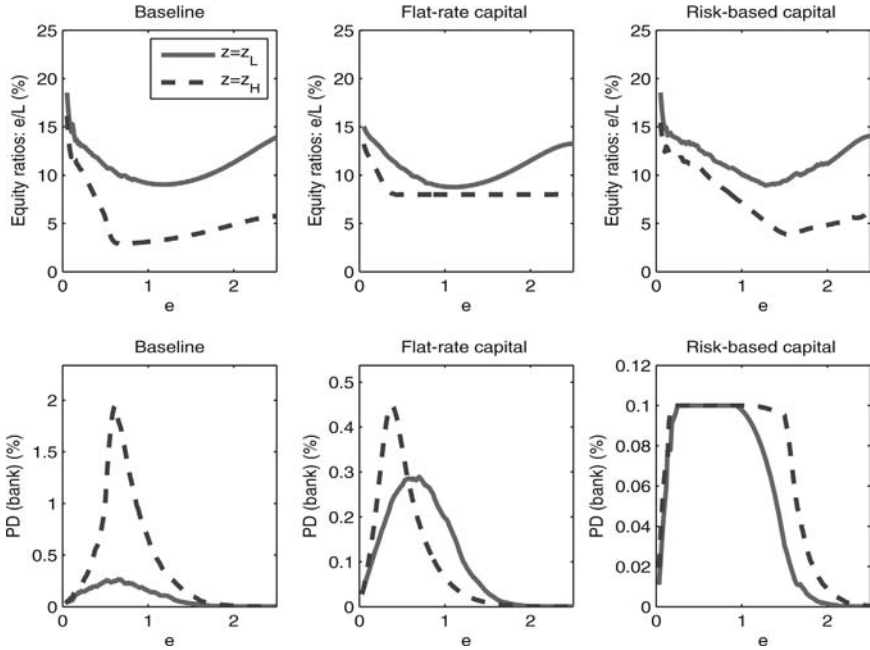

The rest of the paper introduces capital regulation and examines its impact on equilibrium outcomes. The capital requirement is assumed to be exogenously imposed for regulatory reasons that are not explored in this model. Two capital regimes are considered: one is a flat-rate (or risk-insensitive) capital standard that requires a minimum capital/asset ratio of 8 percent, and the other is a risk-based capital rule that ensures a maximum failure probability of 0.1 percent for all banks (defined in equation (2)).

For space reasons, the analysis focuses on the impact of capital regulation on banks' optimal capital structure and the probability of bank failure, as shown in figure 3.²² In general, the imposition of capital regulation has important effects on the bank's financial

²¹In this paper, it is hard to distinguish between the "buildup" and the "materialization" of business risks because all bank loans mature in one period. The simplified assumption on maturity structure misses the realistic situation that there exists a lag for risks to materialize. Therefore, readers should not link directly the realization of bank failures with the state of the business cycle when fitting model predictions with the data. Moreover, for general discussion on the impact of the timing assumption, see Crockett (2000).

²²The equilibrium outcomes under capital regulation are similar to those under the baseline economy. For instance, the bank's franchise value is concave and is strictly increasing in bank size and the state of the economy. In equilibrium,

Figure 3. Equilibrium Outcomes under Capital Regulation

Note: The figure compares the equilibrium equity/asset ratios and equilibrium probability of bank failure under the baseline economy (without capital regulation), under a flat-rate capital regime (a minimum capital/asset ratio of 8 percent), and under a risk-based capital rule (determined by equation (2)).

decisions, but the channel and the magnitude of the effects are quite different under the two capital regimes.

Under a flat-rate capital regime, the capital rule imposes a lower limit on the equity/asset ratio, and its impact on the probability of bank failure is only indirect. Given the countercyclicality of the economic capital, defined as the capital holding under the unregulated economy (see figure 2), the flat minimum capital requirement

all banks choose a cutoff dividend rule as described in proposition 2(ii). Furthermore, large banks tend to lend more and spend fewer resources on monitoring (per unit of asset). These results are not reported but are available upon request.

is more likely to be binding in the good state. Banks are forced to cut lending during the expansion period, and the lower leverage causes the probability of bank failure to be lower than in the baseline economy. By contrast, during downturns the bank's financial decisions are practically unaffected.

The result that capital buffers, defined as actual capital holding minus the minimum capital requirement, are countercyclical under a flat-rate capital rule is consistent with the prediction in Repullo and Suarez (2007) and empirical findings in Ayuso, Pérez, and Saurina (2004) and Stolz and Wedow (2005). Banks hold large capital buffers during economic downturns out of the safety concern, and they hold small capital buffers during upswings. This countercyclical movement in capital buffers has important implications. First, it suggests that capital regulation is useful in containing excessive risk taking at the top of the business cycle. The average loan quality granted during good times is much better than in the baseline economy (lower probability of bank failure), although the improvement is only partial in that the loan risk is still higher during good times (as will be compared with the risk-based capital rule). Second, the fact that the capital constraint is not binding for most banks at the trough of the business cycle suggests that the procyclicality effect may play only a limited role.

Moreover, the cross-sectional difference in economic capital under the baseline economy suggests that the effectiveness of the flat-rate capital rule is different across banks. In good times, the capital constraint is binding for most banks except for the smallest ones. Accordingly, most banks have to reduce the scale of investment to abide by the regulatory constraint. In bad times, banks are willing to hold capital above the minimum regulatory requirement, and the level of capital buffer reflects the difference between economic capital and regulatory capital. Consistent with the baseline results, the very large and very small banks hold larger capital buffers than the others.

Under a risk-based capital rule, the minimum capital requirement is chosen to ensure a minimum level of bank safety (equation (2)). A risk-based capital rule implies that the level of regulatory capital varies not only with the state of the economy but also with the risk profile of bank assets, the latter of which is endogenously determined. Specifically, the new rule rewards banks that have high-quality assets

by lowering their capital requirements and penalizes banks that have low-quality assets by doing the opposite.

The impact of a risk-based capital rule is most obvious if we compare the right-most panels with the left panels in figure 3. The capital regime appears to be quite efficient in improving the safety of individual banks in that the probability of bank failure is successfully contained below the target level. The disciplinary role of the risk-sensitive capital regime is particularly significant in the case of small banks, which are forced by higher capital charges to reduce the scale of bank lending substantially in good times. In other words, the buildup of excessive risk taking by those banks is substantially mitigated. By contrast, large banks' financial decisions are almost unaffected because their strong equity position and low default risk imply that the risk-based capital rule practically imposes no restriction.

An important difference between the two capital rules is their effectiveness over the business cycle. As mentioned above, under the flat-rate capital rule, the capital constraint is more likely to be binding in the good state. By contrast, under the risk-based capital rule, the capital constraint can also be binding in the bad state. This is because, although banks choose a low leverage ratio (in bad times) in the baseline economy, the economy-wide shock is so severe that the bank's probability of failure is still high. As a result, banks have to adjust their lending decisions to meet the safety target specified by the risk-based capital rule. Not surprisingly, among the three economic environments examined in this paper, the variation in bank loan quality over the business cycle (reflected by the probability of bank failure) is the smallest when a risk-based capital rule is imposed.

4.4 The Transition from a Flat-Rate to a Risk-Based Capital Rule

The calibration results permit a reexamination of the impact of the transition from a flat-rate to a risk-based capital regime, including the level of bank capital and the procyclicality issue. I show that the conclusions to the two issues are quite different once one takes into account banks' strategic responses to changes in capital regime, and the impacts are quite different across banks.

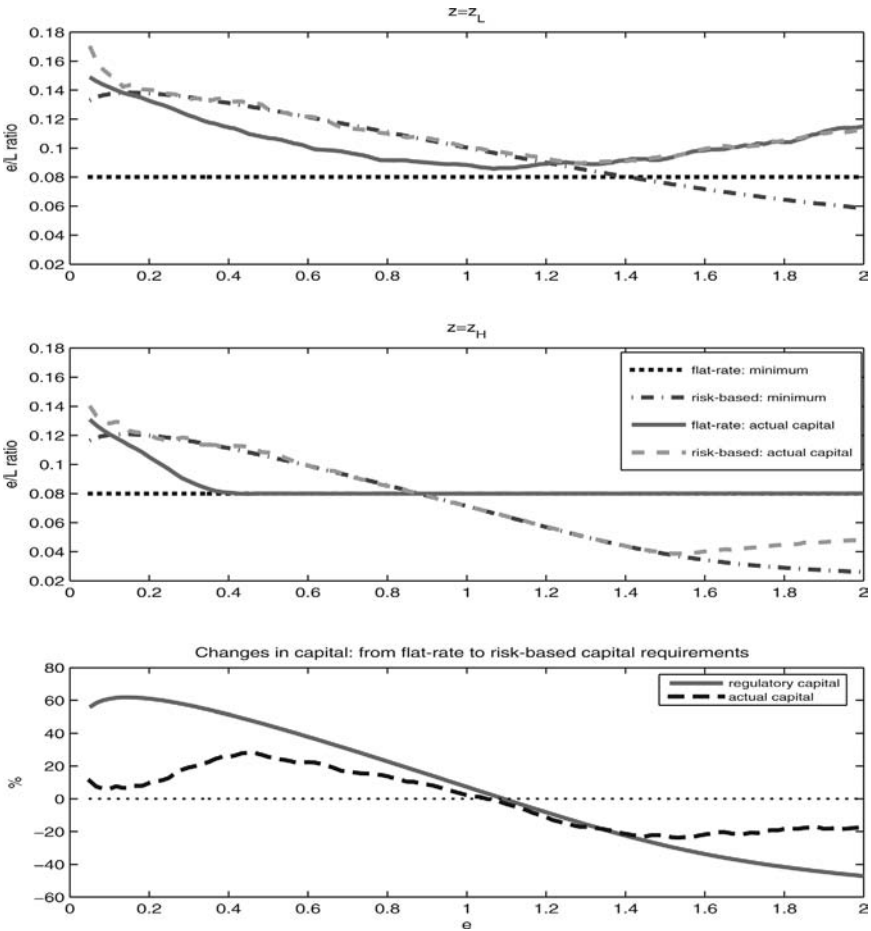

In addressing the first issue, one needs to distinguish between the impact on regulatory minimum requirements and the impact on actual bank capital holdings. The change in regulatory capital is very significant during the transition. The dotted and dash-dotted lines in the top two panels of figure 4, and the solid line in the bottom panel, are indicative of this impact. The risk-sensitive rule favors large (and less risky) banks at the cost of small (and riskier) banks. In particular, it causes the average minimum capital requirement for large banks to be approximately 50 percent lower than under the flat-rate capital regime, and that for small banks to be 50–60 percent higher. These findings are roughly in line with previous studies.

By contrast, the impact of the regulatory rule on actual bank capital holdings is much less pronounced. The solid and dashed lines in the top two panels of figure 4, and the dashed line in the bottom panel, illustrate this impact. Overall, the change in total capital is much smaller than the change in regulatory capital, because of the offsetting effect by endogenous adjustments in banks' capital buffers. Moreover, the impact is less uneven across banks, in that large banks will hold 15–20 percent less capital and small banks will hold approximately 20 percent more capital under the risk-sensitive rule than under the flat-rate one.

The uneven impact across banks is not necessarily undesirable. To some extent, it reflects an important motivation for adopting a risk-sensitive capital regime: to level the playing field. The flat-rate capital requirement does not impose sufficiently high capital requirements on high-risk loans, but at the same time it penalizes high-quality investments. For instance, mid-sized and large banks are forced to forgo high-return, low-risk lending opportunities in good times because of binding capital constraints. By contrast, the risk-based capital regime successfully restores market efficiency by linking capital requirements to asset quality. As the simulation results show, under the risk-based capital regime, the more favorable capital regulation for larger (and safer) banks makes their lending portfolios more similar to those under the baseline economy, while the stricter capital requirement for smaller (and riskier) banks forces them to cut loan extension substantially.

In addressing the second issue, one needs to distinguish between the procyclical movement of bank credit and the procyclicality effect

Figure 4. Comparison of Capital Holdings under Two Capital Regimes

Note: In the top two panels, the dotted and dash-dotted lines plot the minimum capital requirements under two distinctive capital regimes, i.e., a uniform capital/asset ratio of 8 percent or a risk-based capital standard. The solid and dashed lines plot banks' *actual* capital holdings under the two capital regimes. The bottom panel shows the average changes in regulatory capital (solid line) and actual capital (dashed line) if the flat-rate capital rule is replaced by the risk-based capital requirement.

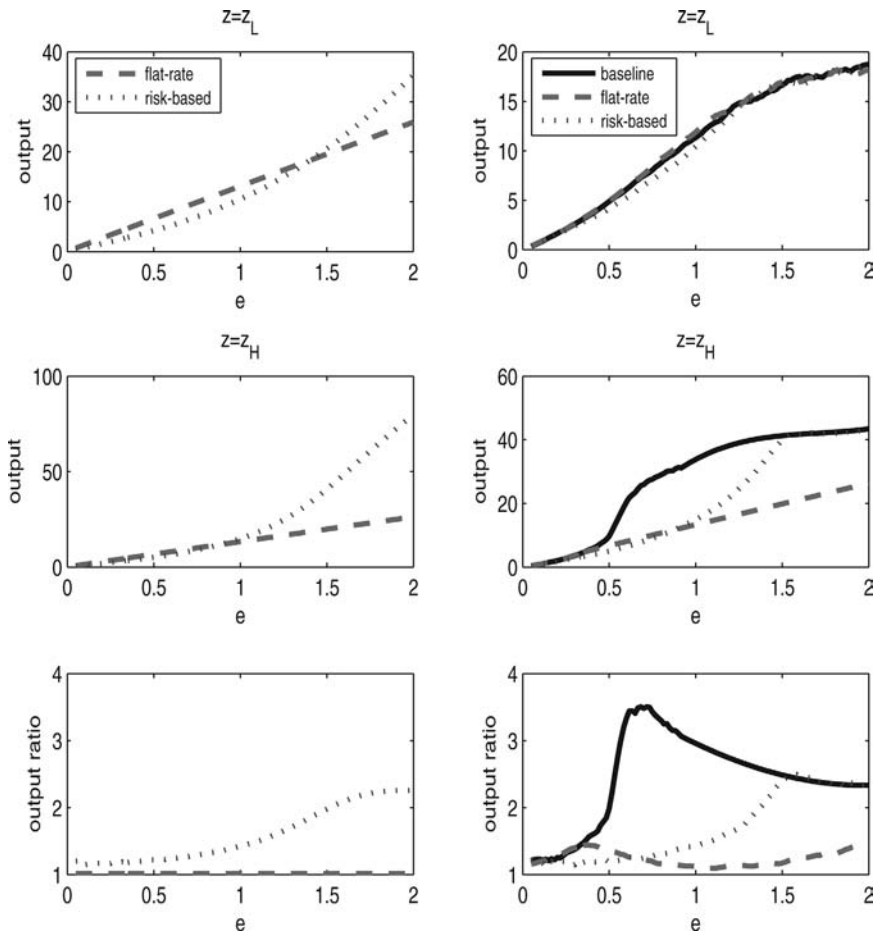

of capital regulation. In particular, the latter refers to *excessive* volatility of bank credit as a result of introduction of capital regulation, compared with the cyclic movement under the unregulated economy. Such distinction is important, because a cyclical movement of bank credit itself could be a manifestation of an optimal allocation of economic resources over the business cycle. By contrast, excessive volatility of bank credit, which in the context of this model is equivalent to an amplified cycle of economic output, could cause potential harm to the real economy and should be avoided.

In this paper, I quantify the magnitude of credit cycle for each bank by calculating the ratio of economic outputs (lending revenue minus the monitoring cost) in good times versus in bad times (shown in the lower right panel in figure 5). Furthermore, under capital regulation, the cycle is further broken down into two components—one attributed to the cyclical movements in capital charges (shown in the lower left panel in figure 5) and the other driven by variation in capital buffers. The comparison of credit cycles between the baseline economy and the one with capital regulation sheds light on the procyclicality effect of capital requirements. Several major observations arise from the calibration results.

First, under both capital regimes, *actual* economic outputs co-move with the business cycle, but the amplitude of the lending cycle is much less volatile than in the baseline economy. This points to an important message that the concern about the procyclicality effect might have been misplaced from the beginning, in that neither the flat-rate nor the risk-based capital regime brings excessive volatility in economic activity. Instead, both capital regimes have a mitigating effect on the cyclical movement in bank credit, because capital regulation constrains banks' excessively risky lending during upswings. It is therefore misleading to label the procyclical movement in bank credit, which is a reflection of the change in investment productivity, as an undesirable effect caused by capital regulation.

Second, the driving forces behind the procyclical movement in bank credit are quite different under the two capital regimes. Under the flat-rate capital requirement (the dashed lines in the upper and middle panels in figure 5), this co-movement is mainly driven by the anticyclical movement in capital buffers, while the capital constraint

Figure 5. Lending Cycles under Two Capital Regimes

Note: The figure plots the level of economic output (lending revenue minus the monitoring cost) for each bank under two distinctive capital regimes, i.e., a uniform capital/asset ratio of 8 percent (dashed lines) or a risk-based capital standard (dotted lines). The left panels refer to the results if banks choose portfolios as indicated by the minimum capital requirements, and the right panels refer to actual outcomes in equilibrium (equilibrium outputs under the baseline economy are also shown in dark lines for comparison purpose). The bottom panels plot the ratio of outputs in the good state versus in the bad state, a measure for the magnitude of lending cycles.

has only a small impact because it merely reflects the difference in the economy-wide shock. By contrast, under the risk-based capital regime, the swing in economic activity is mainly driven by the countercyclicality of capital charges, and the variation in capital buffers has hardly any impact.²³ To some extent, this difference implies that the risk-based capital rule achieves the goal of aligning regulatory capital with actual capital that a bank is willing to hold.

Lastly, the actual cyclic movement of lending activity tends to be bank specific because of distinction in banks' financial decisions. Under the flat-rate capital regime, banks that hold low capital buffers in both states (initial equity ≈ 1) have the smallest credit cycle in the banking industry. Under the risk-based capital regime, the cyclical swing in lending activity is most remarkable for largest banks, as their low risk profile (due to the strong equity position) implies that they are practically not constrained by the capital rule and hence their lending fluctuates freely, reflecting the change in productivity over the business cycle.

Importantly, these results suggest that it is unclear whether the transition toward a risk-sensitive capital rule would amplify or mitigate the credit cycle in the aggregate economy. The calibration results show that the cycle for very small banks is less pronounced under the risk-sensitive capital rule, whereas it becomes more volatile for large banks. The aggregate effect, therefore, depends on the size distribution of the banking industry. For instance, the simulation results in figure 5 suggest that the aggregate credit cycle is less pronounced under the risk-based capital standard than under the flat-rate capital rule if the majority of assets in the banking industry are held by very small banks, and vice versa if large and medium banks play a dominant role.

²³The large swing in minimum capital requirements is driven partly by the short horizon of the portfolio risk assessment. For simplicity reasons, this model assumes that bank assets mature in one period (or one year); therefore, the risk profile of a bank's portfolio is a point-in-time measure. This is consistent with the prevalent practice of using one-year default probability in computing risk-based capital requirements. If risk assessments over a longer time horizon are adopted (e.g., "through-the-cycle" ratings), the variation in regulatory capital over time tends to be smoother. This requires a richer maturity structure of bank assets in a dynamic setting, which is beyond the scope of this paper.

5. The Trade-Off between Efficiency and Safety and the Impact of Capital Regimes

The previous section discusses how the change in capital rules affects banks' equilibrium financial decisions. Nevertheless, there is no indication whether this change is desirable. For instance, lower leverage and higher bank safety are not always appealing if they imply a big sacrifice in lending efficiency and growth potential. The analysis in this section can shed some light on this important issue.²⁴

Although there is no consensus on the objective function of a bank regulator, researchers tend to agree that the introduction of capital regulation can be justified on the basis of improving the safety and soundness of the banking sector and minimizing negative externality associated with bank failure. Following the mainstream of the literature (see, e.g., Dell'Ariccia and Marquez 2006; Hellman, Murdock, and Stiglitz 2000; and Kashyap and Stein 2004), I assume that there are two major components in a regulator's objective function: franchise value and the probability of bank failure, which stand for the the profitability (or efficiency) and safety of the banking sector, respectively. For obvious reasons, the regulator favors higher franchise value and lower bank fragility.

There are two ways for a regulator to examine the welfare implications of capital regulation—a *micro* perspective that draws conclusion from the analysis based on individual banks, and a *macro* perspective that focuses on the banking system as a whole. This is in line with the two distinct views regarding the objective of prudential regulation, known as the micro- and macro-prudential perspectives.²⁵ The first view emphasizes the safety of *individual* financial institutions, with an implicit assumption that the safety of individual banks is a sufficient and necessary condition for the

²⁴The following discussion focuses exclusively on two capital regimes examined in this paper. Implicitly, I assume that a regulator only cares about franchise value and bank fragility but nothing else, and he or she is fully aware of banks' responses to various capital rules. The discussion is not intended to address the issue of optimal design of capital regulation.

²⁵See Crockett (2000) and Borio (2003) for further discussion. Nevertheless, the distinction between the two strands of views is not always clear-cut.

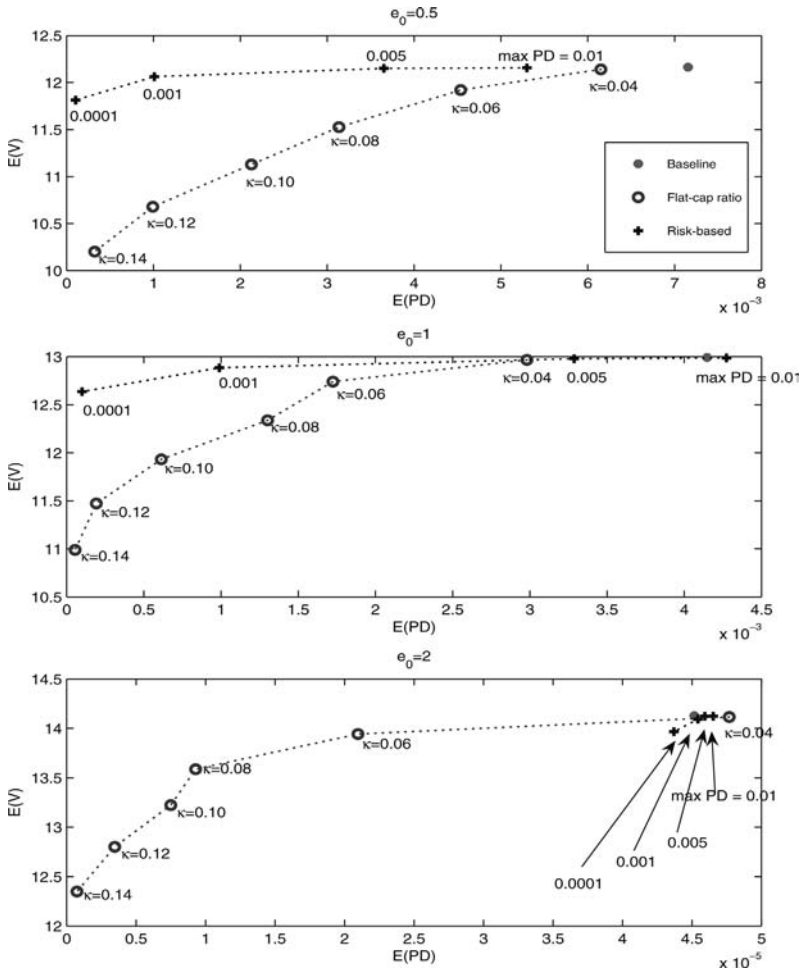

soundness of the banking system. By contrast, the macro perspective analyzes the financial system as a whole. Therefore, systematically more important banks receive more attention from the regulator than small banks that contribute less to the systemic risk.

Figure 6 illustrates the impact of the two capital regimes on the trade-off between efficiency and safety from a micro perspective, using a very small bank (initial equity $e_0 = 0.5$), a small bank ($e_0 = 1$), and a large bank ($e_0 = 2$) as examples. The horizontal axis represents the expected probability of bank failure and the vertical axis represents expected franchise value, using the fact that the good and bad states are equally likely to occur in the long run. The exercise is implemented by studying the flat-rate capital regime with different minimum capital ratio requirements ($\kappa = 2\%, 4\%, \dots, 14\%$) and the risk-based capital regime with different threshold default probabilities (based on the credit VaR definition as specified in equation (2)).

The results are interesting. When the capital standard is very loose, the equilibrium outcome converges to the result under the baseline economy. And the tightening in capital standards (higher uniform capital ratios or lower threshold default probabilities) moves the equilibrium outcome to the lower-left corner. That is, it reduces the probability of bank failure at the cost of banks' franchise value. This is not surprising, since the regulator puts more emphasis on bank safety relative to efficiency. The more interesting finding is that the risk-based capital rule usually yields a higher franchise value for the same degree of bank safety. This implies that the risk-based capital regulation is more appealing from a regulator's perspective. At first glance, this result is not quite intuitive. For instance, comparing the flat-rate capital requirement with $\kappa = 8$ percent and the risk-based capital requirement with the threshold default probability at 0.1 percent, a small bank actually faces a more restrictive capital requirement under the second regime and is forced to choose lower leverage and a lower probability of failure in the current period. However, the bank has a higher franchise value under the risk-sensitive regime than under the flat-rate regime, despite the current-period losses.

The answer to this seeming puzzle lies in the dynamic benefit from the risk-based capital regulation. As I mentioned earlier,

**Figure 6. Comparison between the Two Capital Regimes:
A Micro Perspective**

Note: This figure plots expected franchise value and expected probability of failure for a very small bank (initial equity of 0.5, the top panel), a small bank (initial equity of 1, the middle panel), and a large bank (initial equity of 2, the bottom panel), with the good and bad states equally likely to occur in the long run. The circles refer to equilibrium outcomes under flat-rate capital requirements, with minimum capital ratios varying from 4 percent to 14 percent. The “+” symbols refer to equilibrium outcomes under the credit VaR-based capital regulation, with threshold default rates varying from 1 percent to 0.01 percent.

a potential problem with the flat-rate capital rule is that it is not capable of discriminating between sound loans and risky loans; therefore, it tends to hamper efficiency as when it reduces bank fragility. This is most obvious in the case of large banks (the bottom panel), which are forced to forgo sound investment opportunities in order to achieve a very low probability of failure. This conservative lending strategy is no longer appealing, because efficiency losses are too high. From a dynamic perspective, it implies that all banks pay a very high future franchise-value cost under the flat-rate capital regime. This cost tends to overshadow any potential one-period expected gains (as in the small-bank example above) and cause expected franchise value to be significantly lower than under a risk-based capital regime.

In addition, figure 7 illustrates the comparison from a macro perspective, based on a hypothetical banking sector that consists of five large banks ($e_0 = 2$) and fifty small banks ($e_0 = 1$).²⁶ Bank-specific shocks are assumed to be independent across banks. The horizontal axis represents the fragility of the whole banking sector, defined as the probability that more than 5 percent of total bank assets default in the current period. In this example, the threshold is equivalent to the failure of one of the five large banks or the failure of four small banks simultaneously. In this simplified banking sector, the comparison result between the two capital regimes is in line with the micro-based results. The risk-based capital requirement achieves a better balance between lending efficiency and safety, in that (expected) aggregate franchise value is higher for any given level of banking stability.

Clearly, this is only an illustrative example, and the results should not be interpreted as general and conclusive. There are many complicated issues related to a practical implementation of this method, but these issues are beyond the scope of this paper. For instance, the results depend crucially on the size distribution of the banking sector and the interdependence of asset returns across banks, both of which are not explored in this paper.

²⁶In equilibrium, the concentration ratio of the top five banks is about 30–40 percent, which is in line with the survey results in the United States and other industrial countries (see Bank for International Settlements 2004, 131).

A Macro Perspective**

Note: This figure plots expected franchise value and expected probability of failure for a group of banks that consist of five large banks (initial equity of 2) and fifty small banks (initial equity of 1), with the good and bad states equally likely to occur in the long run. The horizontal axis represents the probability that more than 5 percent of total bank assets default in one period, and the vertical axis represents total franchise value. The circles refer to equilibrium outcomes under flat-rate capital requirements, with minimum capital ratios varying from 4 percent to 14 percent. The “+” symbols refer to equilibrium outcomes under the credit VaR-based capital regulation, with threshold default rates varying from 1 percent to 0.001 percent.

6. Concluding Remarks

This paper develops a dynamic equilibrium model and examines the impact of the transition from a flat-rate to a risk-sensitive capital

regulation on banks' financial decisions. Several important policy implications arise. First, in gauging the impact, it is important to take into consideration the potential influence on banks' capital buffers and portfolio decisions. I show that the change in actual capital holdings is much smaller than the change in regulatory capital. Second, the impact of the capital regime differs substantially across banks. The risk-sensitive capital standard leads to a more favorable capital requirement for large (and in this model also less risky) banks. Hence, the cyclical movement in lending behavior is more remarkable for these banks. By contrast, small (and riskier) banks are subject to a stricter capital regulation under the new regime. They have to cut loan extension substantially in good times, when risk is most likely to build up in the absence of regulatory restrictions. As a result, the lending cycle for these banks is actually less volatile under the risk-sensitive regime. Lastly, the analysis suggests that the transition might be welfare improving from a regulator's perspective, in that the risk-based capital regime finds a better balance between safety and efficiency and causes less distortion in loan decisions.

The analysis provides a starting point to examine issues regarding the design of bank capital regulation and the interaction between the banking sector and the real economy. It is by no means a completed task. One caveat of this model is that the asset side of the bank's balance sheet is not explicitly modeled, for the sake of isolating the potential cyclicity coming from the supply side of the bank loan market. This model, however, can serve as a building block for a full dynamic stochastic general equilibrium model with a production sector composed of entrepreneurial firms that rely on relationship bank lending. There are good reasons to believe that the main arguments in this paper will remain valid in the more general setting.

In a dynamic general equilibrium model in which firms do not have alternative funding sources to bank loans, banks' financial decisions will have an important feedback effect on firms' investment decisions. A countercyclical movement in regulatory capital, as specified by a risk-based capital rule, tends to interact with the feedback effect and exacerbate the fluctuations in economic activity. Importantly, this amplification mechanism builds on the assumption that the minimum capital requirement is binding during economic downturns.

The results in this paper do not question the soundness of the above argument. Nevertheless, the results suggest that the above spiral effect can be mitigated for several reasons. First, the assumption that capital constraints are binding during economic downturns is debatable. If banks hold capital buffers at the trough of the business cycle, as shown in this paper, the above amplification mechanism tends to be much smaller. Second, the above argument ignores the positive role of capital regulation in containing excessive risk taking during economic upswings, or the risk buildup period. As shown in this paper, the binding capital constraint in good times may be equally important in containing excessive output fluctuation over the business cycle. Last, but not least, this paper suggests that it is very important to take into account banks' optimal financial decisions. In a general equilibrium model in which the above amplification mechanism is effective, the cost associated with a binding capital constraint during economic downturns is much higher. This will increase banks' incentive to hold more capital buffers. Therefore, it is still important to examine banks' endogenous capital buffer and portfolio decisions in a full-blown dynamic stochastic general equilibrium model.

Appendix

Proof of Proposition 1

(i) The dynamic program problem is equivalent to

$$V(e_t, z_t) = \max_{(L_t, \mu_t, e_{t+1})} \sum_{z_{t+1}} \left\{ \int_{\bar{\epsilon}}^{\infty} [d(\pi_t, e_{t+1}) + \beta V(e_{t+1}, z_{t+1})] \phi(\epsilon) d\epsilon \cdot P(z_{t+1} | z_t) \right\} \quad (15)$$

subject to equations (6), (7), (8), (10), (11), and (13).

It suffices to prove the existence of a unique solution V^* by showing that the $V(\cdot)$ function satisfies the two Blackwell's sufficient conditions and therefore is a contraction mapping. To check the two conditions, perform the following steps:

- (*Monotonicity*) Take $V_1 \geq V_2$, then

$$\begin{aligned} T(V_1) &= \max E[d(L^*, \mu^*, e^*) + \beta V_1(e^*, z_{t+1})] \\ &\geq \max E[d(L^*, \mu^*, e^*) + \beta V_2(e^*, z_{t+1})] \\ &= T(V_2). \end{aligned}$$

- (*Discounting*) For any positive real number $c > 0$,

$$\begin{aligned} T(V + c) &= E\{d(L^*, \mu^*, e^*) + \beta[V(e^*, z_{t+1}) + c]\} \\ &= E\{d(L^*, \mu^*, e^*) + \beta V(e^*, z_{t+1})\} + c \\ &= T(V) + c. \end{aligned}$$

- (ii) The concavity of the $V^*(e)$ function can be proved based on theorem 4.8 in Stokey, Lucas, and Prescott (1989, 81). For simplicity, I only prove the case in which z is constant, but the proof can easily be extended to the case in which z is random.

First, it is straightforward that the $d(\pi_t, e_{t+1})$ function is continuous and bounded if we can restrict feasible values of e within the range $[e_{min}, e_{max}]$, where $e_{min} = 0$ and e_{max} is sufficiently large so that banks' equity position will never exceed the boundary.

Second, the $d(\cdot)$ function is concave. That is, for any (π_1, e'_1) , (π_2, e'_2) and all $h \in [0, 1]$,

$$d(\pi_3, e'_3) \geq hd(\pi_1, e'_1) + (1 - h)d(\pi_2, e'_2),$$

where $\pi_3 \equiv h\pi_1 + (1 - h)\pi_2$ and $e'_3 \equiv he'_1 + (1 - h)e'_2$. This is because of the following:

- If $\pi_1 \geq e'_1$ and $\pi_2 \geq e'_2$, then $\pi_3 \geq e'_3$ and $d(\pi_3, e'_3) = hd(\pi_1, e'_1) + (1 - h)d(\pi_2, e'_2)$.
- Similarly, if $\pi_1 < e'_1$ and $\pi_2 < e'_2$, then $\pi_3 < e'_3$ and $d(\pi_3, e'_3) = hd(\pi_1, e'_1) + (1 - h)d(\pi_2, e'_2)$.

- If $\pi_1 \geq e'_1$, $\pi_2 < e'_2$, and $\pi_3 \geq e'_3$, then

$$\begin{aligned} d(\pi_3, e'_3) &= h(\pi_1 - e'_1) + (1 - h)(\pi_2 - e'_2) \\ &> h(\pi_1 - e'_1) + (1 - h)(1 + \lambda)(\pi_2 - e'_2) \\ &= hd(\pi_1, e'_1) + (1 - h)d(\pi_2, e'_2). \end{aligned}$$

- If $\pi_1 \geq e'_1$, $\pi_2 < e'_2$, and $\pi_3 < e'_3$, then

$$\begin{aligned} d(\pi_3, e'_3) &= h(1 + \lambda)(\pi_1 - e'_1) + (1 - h)(1 + \lambda)(\pi_2 - e'_2) \\ &> h(\pi_1 - e'_1) + (1 - h)(1 + \lambda)(\pi_2 - e'_2) \\ &= hd(\pi_1, e'_1) + (1 - h)d(\pi_2, e'_2). \end{aligned}$$

Finally, the feasible set of e' is convex if we restrict the feasible value of e within $[e_{min}, e_{max}]$.

Based on the above three properties, the $V^*(e)$ function is strictly concave in e .

Proof of Proposition 2

To determine the optimal monitoring effort in the current period, it is worth noticing that future bank value, $V(e_{t+1}, z_{t+1})$, is independent of μ_t . Therefore, the optimal μ_t should maximize

$$\int_{\bar{\epsilon}}^{\tilde{\epsilon}} (\pi_t - e_{t+1})(1 + \lambda)\phi(\epsilon)d\epsilon + \int_{\tilde{\epsilon}}^{\infty} (\pi_t - e_{t+1})\phi(\epsilon)d\epsilon, \tag{16}$$

where $\tilde{\epsilon}$ is the critical value below which new equity needs to be raised. It is determined by $(\tilde{\epsilon} - \bar{\epsilon})F(L) = e_{t+1}$.

The first-order condition of the maximization problem can be rearranged as

$$\frac{d\bar{\epsilon}}{d\mu} \cdot [e_{t+1}(1 + \lambda)\phi(\bar{\epsilon}) - (1 + \lambda)F(L)(\Phi(\tilde{\epsilon}) - \Phi(\bar{\epsilon})) - F(L)(1 - \Phi(\tilde{\epsilon}))] = 0.$$

Since the bank chooses μ_t at the beginning of period t , at which time the choice of e_{t+1} is still uncertain, the above condition is satisfied if and only if $\frac{d\bar{\epsilon}}{d\mu} = 0$. From equations (4) and (5), it is straightforward to derive that $\frac{d\bar{\epsilon}}{d\mu} = \frac{\theta'(\mu)L - F(L)}{(1 - \Phi(\bar{\epsilon}))F(L)}$. Therefore,

$$\left. \frac{d\bar{\epsilon}}{d\mu} \right|_{\mu=\mu^*} = 0 \quad \Rightarrow \quad F(L) = \theta'(\mu^*)L. \tag{17}$$

In addition, given the strict concavity of V^* , the dividend policy assumes a cutoff rule for a given initial bank equity. Since this is quite straightforward, I leave out the strict proof here, but the intuitions are described in the text.

Computational Procedure

The computational procedure for the dynamic programming is based on value function iteration as introduced in Judd (1998). The value function is solved based on the discretization of the state variable e_t , the quasi-state variable π_t , and control variables L_t and e_{t+1} . The main features of the numerical algorithm are as follows:

- Set the minimum and maximum values of bank equity (e) and end-of-period net profit (π).
- The range of bank lending (L) is set within $[e, e/\kappa]$ under the flat-rate capital requirement or within $[e, L_{max}]$ under the risk-based capital regime (L_{max} is calculated from equation (2) by setting $e_{min} = e$).
- For each pair of (e, L) , calculate the corresponding \bar{e} and μ based on equations (6) and (7) and proposition 2(i).
- For each pair of (e, L) , calculate the probability distribution of end-of-period net asset values.
- Guess initial values of the $V(e)$ function for $z = z_H$ and $z = z_L$.
- Solve for the $W(\pi, z)$ function and the policy function e' for given π , e , and z .
- Based on the W function, solve for the $V(e, z)$ function and the policy function L for given e and z . The found values are the new guesses of the V function. The procedure is then restarted from the previous step until converged.
