

Unintended Consequences of U.S. Monetary Policy Shocks: Dutch Disease and Capital Flow Measures in Emerging Markets and Developing Economies*

Juan F. Yépez
International Monetary Fund

Dutch disease is often referred to as a situation in which large and sustained foreign-currency inflows lead to a contraction of the tradable sector by giving rise to a real appreciation of the home currency. This paper documents that this syndrome has been witnessed by several emerging markets and developing economies (EMDEs) as a result of sharp surges in capital inflows driven by accommodative U.S. monetary policy after the global financial crisis. In a sample of 25 EMDEs from 2000 to 2017, the loosening of U.S. monetary policy usually coincided with episodes of significant currency appreciation and a contraction in tradable output in these economies. The paper also shows empirically that the use of capital flow measures (CFMs) has been a common policy response in several EMDEs, and CFMs are somewhat effective in insulating these economies from U.S. monetary policy shocks. The paper also presents a two-sector small open economy augmented with a learning-by-doing (LBD) mechanism in the tradable sector to rationalize these empirical findings. A welfare analysis provides a rationale for the use of CFMs as a second-best policy when agents do not internalize the LBD externality of costly

*I would like to thank Linda S. Goldberg, the editor, and two anonymous referees for suggestions that greatly improved the paper. I am also grateful to Martin Čihák, Fabián Valencia, Bas Bakker, Francesco Grigoli, Marcin Kolasa, Nicolás Magud, Jorge Roldós, and seminar participants at the IMF for helpful comments. The views expressed in this paper are those of the author and do not necessarily represent the views of the IMF, its Executive Board, or IMF management.

resource misallocation. However, the adequate calibration of CFMs and the accurate quantification of the LBD externality represent important implementation challenges.

1. Introduction

Ultra-accommodative monetary policies in advanced economies, particularly in the United States, have had considerable spillover effects on emerging economies (Rey 2013; Kalemli-Özcan 2019). Investors, in search of a higher yield, shifted their portfolios to many emerging markets and developing economies (EMDEs) in higher proportions during the past decade and a half (Figure 1, panel 1). While the greater availability of foreign capital during episodes of low U.S. monetary policy rates supported growth through better risk sharing and increased technology transfer, the sheer magnitude and cyclical nature of capital inflows amplified domestic imbalances and led to currency appreciation across several EMDEs (Figure 1, panel 2). Amid rising macroeconomic imbalances and uncertainty over the sustainability of capital inflows, EMDEs in several cases resorted to capital flow management measures (CFMs) mainly after the global financial crisis (GFC), reverting almost a decade-long process of gradual capital account liberalization (Figure 1, panel 3).

Given the increased prevalence in the use of CFMs across EMDEs over the past two decades (Fernández et al. 2016), studies have focused on an externality view of CFMs in order to justify the use of these policy tools.¹ The common theme of this strand of literature is that capital flows may generate externalities that private agents do not internalize, with the externalities emphasized by this work being mainly financial in nature. The presence of these externalities induces private agents to borrow too much (*ex ante*), to buy too little insurance or take on excessive risk, and to borrow excessively short term. However, a recent strand of the literature has started to look at the implications of capital inflows on the allocation of resources across industries (Reis 2013; Benigno and Fornaro 2014;

¹See Erten, Korinek, and Ocampo (2021) for a detailed overview of the “externality” literature on CFMs.

Figure 1. Capital Inflows, REER, and CFMs in EMDEs and the U.S. Monetary Policy Rate

Note: The horizontal dashed lines represent the period average of the Wu and Xia (2016) shadow U.S. federal funds rate. The three periods illustrated are the pre-GFC (2001–07); post-GFC (2008–14); and U.S. policy liftoff period (2015–19). The Wu and Xia (2016) shadow federal funds rate is a proxy for the U.S. monetary policy rate; it accounts for the zero lower bound and the macroeconomic effects of unconventional monetary policy in the United States after the GFC. Panels 2 and 3 denote simple averages for the REER and CFM across 25 EMDEs. Please see next section for sample and data details.

Saffie, Varela, and Yi 2020). This literature links inflows to a contraction (expansion) of the tradable (non-tradable) sector by giving rise to a real appreciation of the home currency, a situation often referred to as Dutch disease.

The appropriate policy mix for addressing the macroeconomic risks to which surges in capital inflows can give rise depends on a variety of country-specific considerations. According to the International Monetary Fund's (IMF's) Institutional View on the Liberalization and Management of Capital Flows adopted in 2012 (see IMF 2012), the use of CFMs may be appropriate during surges in capital inflows if the currency becomes overvalued and reserves are adequate, making exchange rate intervention undesirable. This would be the case, for example, if there are resource reallocation frictions across the economy and Dutch disease effects emerge (see Lama and Medina 2012; IMF 2022). At the same time, lowering interest rates during a Dutch disease episode can create overheating pressures and higher macroeconomic volatility and welfare costs.

This paper seeks to examine the merits of the use of CFMs as a policy intervention tool to alleviate possible Dutch disease effects stemming from capital inflows. Specifically, the paper makes three contributions: (i) it empirically documents that Dutch disease in EMDEs was a common side effect of U.S. monetary policy shocks; (ii) the paper shows that the use of CFMs in response to U.S. interest rate shocks was common across EMDEs and often helped in limiting Dutch disease effects in these economies; and (iii) the paper rationalizes these empirical findings in a dynamic stochastic general equilibrium (DSGE) model and evaluates the welfare implications of using CFMs to prevent costly resource misallocation as a result of Dutch disease.²

To document the presence of Dutch disease episodes, the empirical section of the paper estimates the effects of U.S. monetary policy shocks on the currencies and tradable output of a sample of 25 EMDEs. The empirical strategy is centered around U.S. monetary policy shocks, as these have been the main drivers of capital flows

²The term “Dutch disease” was first introduced by the *Economist* in 1977 to describe the economic crisis in the Netherlands in the 1960s following the discovery of North Sea natural gas deposits. More recently, the term is also used to describe the effects on the tradable sector induced by remittances, foreign aid, terms-of-trade shocks, and capital inflows (see Kojo 2014).

by non-residents to EMDEs (see Milesi-Ferretti and Tille 2011; Shin 2012; Rey 2013; among others). Also, U.S. monetary policy can be assumed to be exogenous to innovations in the currencies and tradable output of EMDEs, which allows for a more precise statistical identification of the spillover effect of these policy shocks on EMDEs.

The paper also documents the evolution of restrictions to capital account transactions following U.S. monetary policy shocks. It does so by exploiting a set of measures of capital account restrictions developed by Fernández et al. (2016).³ Given the inherent endogeneity of CFMs, the effects of U.S. monetary policy shocks on EMDEs are estimated within a system of regressions using a panel vector autoregression (PVAR) framework. The CFM index is treated as an endogenous variable in this framework. Results are summarized in the form of impulse responses within a five-year horizon.

The results suggest that U.S. monetary policy shocks led to statistically significant Dutch disease effects in EMDEs after the GFC. In the post-GFC period, one year after a 1 percentage point reduction in the U.S. monetary policy rate, currencies appreciate significantly and the share of tradable output in total GDP decline by around half a percentage point. The currency appreciation is somewhat temporary, but the decline in tradable output is relatively more persistent. In terms of policy response, EMDEs tend to increase the number of capital flow restrictions on inflows after U.S. monetary policy shocks, with the tightening of CFMs in some cases lasting for several years. In addition to these baseline results, the paper also presents evidence that Dutch disease effects were more significant in EMDEs with more flexible exchange rates and occurred in commodity and non-commodity exporting economies. While the paper does not find evidence of Dutch disease effects in advanced economies (AEs), the use of CFMs in these economies was common during periods of more accommodative U.S. monetary policy. These results are robust to the use of alternative measures of U.S. monetary policy shocks, CFM measures, and when controlling for other macroeconomic variables such as real investment growth.

³This index uses information from the IMF's Annual Report on Exchange Arrangements and Exchange Restrictions (AREAER). This is one of the few indices that distinguishes between CFMs on inflows and outflows and provides a unified framework to measure the intensity of CFMs across countries.

Against the backdrop of these empirical findings on how U.S. monetary policy shocks gave rise to Dutch disease effects in the aftermath of the GFC and the use of CFMs in EMDEs, the paper explores whether the use of CFMs was effective in limiting to some extent the currency appreciation and contraction of the tradable sector in EMDEs. By conditioning the responses of currencies and tradable output to U.S. monetary policy shocks with the level of CFMs, a key finding of this paper is that countries with higher capital account openness experienced larger currency appreciation and a larger contraction of tradable output. Given the endogeneity of CFMs and possible reverse-causality concerns, and in order to assess the optimality of the use of CFMs in addressing Dutch disease effects, the empirical findings are qualitatively matched using a dynamic stochastic general equilibrium (DSGE) model.⁴

The DSGE model consists of a representative household and two sectors (tradable and non-tradable). Households have access to international credit markets, but they are subject to a tax on interest rate payments (i.e., a CFM) on external debt (as in Kitano 2011). The model is based on a small open economy assumption, which is that households take the interest rate on foreign debt as given and firms have no effect on the price of tradable goods. As in the empirical analysis, impulse responses are calculated for a negative shock to the global interest rate. To assess the welfare implications of using CFMs to limit Dutch disease effects, model simulations are conducted for various tax rates on foreign debt service.

Results from the model simulations suggest that there is indeed a role for CFMs in limiting Dutch disease following a shock to the global interest rate. A tax on foreign debt service raises the cost of foreign capital and discourages foreign borrowing. The lower availability of foreign capital in turn attenuates the appreciation of the currency and a reallocation of resources from the tradable to the non-tradable sector. This effect is achieved by limiting the increase in the relative price of non-tradables (as compared to a regime with

⁴A number of authors have called into question the merits of DSGE models in policy analysis (see Blanchard 2018 and the discussion therein). However, a data-based DSGE model is a powerful tool to illustrate the effects of a well-identified exogenous shock and to assess the effects of a systematic policy change (see Christiano, Eichenbaum, and Trabandt 2018).

no CFMs). Against this background, the model does a good job in qualitatively matching Dutch disease effects arising from a sudden reduction in the U.S. monetary policy rate observed in the data and showing how CFMs could limit these effects in a small open economy.

In a standard frictionless two-sector real business-cycle model, the reallocation between the tradable and non-tradable sector, such as the one described above, is the efficient response to an increase in the availability of foreign capital. Higher credit access following a reduction in global interest rates will increase the demand for tradable and non-tradable goods, and as a consequence wages will be higher in the economy. Since the model takes international prices as given, higher wages will reduce the production of tradable goods, and the demand will be satisfied with imports from the rest of the world. In this situation there is no rationale for government intervention, and protecting the tradable sector will reduce overall welfare.

A common friction commonly discussed in the Dutch disease literature, and the focus of the theoretical section in this paper, is a learning-by-doing (LBD) externality in the tradable sector. The LBD technology augments the productivity of the tradable sector, and represents a cost to the reallocation of resource away from this sector. By augmenting the model to include an LBD mechanism, a reduction in tradable output will lead to lower productivity in that sector and a decrease of future production. If this mechanism is not internalized by the firms, then there will be an inefficient loss of tradable production and hence a role for policy intervention. This paper focuses on the merits of CFMs as a second-best policy in the presence of an LBD externality.⁵

One of the main insights of this paper is that the use of CFMs on inflows could be a welfare-increasing policy to counteract the effects of the Dutch disease in the presence of an LBD externality. By preventing a large appreciation of the currency stemming from surges in capital inflows generated by U.S. monetary policy shocks, CFMs can prevent a contraction of tradable production below the efficient level. Under standard calibration parameters, the theoretical analysis of the paper finds that limiting the increase in the relative price of non-tradables prevents an inefficient reallocation of resources away from

⁵The first-best (i.e., the social planner's) solution would be the one in which the externality is removed and agents internalize the cost of resource reallocation.

the tradable sector, with this in turn leading to higher total output in the long-term and to an increase in households' welfare. These conclusions are robust to different levels of the LBD externality.

The importance of an LBD externality hinges on the assumption that the tradable sector is the sole contributor to LBD, which may clearly be a realistic approximation for some EMDEs, and equally unrealistic for others. In this regard the use of CFMs to address Dutch disease effects would be most suitable for EMDEs with a sizable manufacturing export sector, a sector identified in the literature as the one in which LBD accrues the most. However, the use of CFMs could be subject to trade-offs. While policies aimed at preventing surges in capital inflows could be appropriate in the presence of an LBD externality, they could amplify macroeconomic volatility in the presence of other frictions, such as nominal rigidities in other sectors. However, given that in many EMDEs monetary policy frameworks are still evolving and inflation expectations are not strongly anchored, policies that enable policymakers in these economies to avoid sharp currency fluctuations and prevent undue losses in tradable output are likely to dominate other policy alternatives.

The results presented in this paper also highlight that there are important implementation challenges, as the benefits of CFMs could be large but for a narrow region of the tax. This means that policymakers need to carefully calibrate the magnitude of CFMs, otherwise the gains from these policies become very small. Furthermore, the fact that the LBD externality is not observable and difficult to measure, calibrating an appropriate CFM response (not only regarding their magnitude but also their duration) could be a challenging endeavor for policymakers.

Related Literature. The empirical section of the paper adds to a relatively recent literature documenting that in middle-income economies, expansions owing to capital inflows lead to resources shifting away from tradable activities (see, for example, Tornell and Westermann 2005; Reis 2013; Benigno and Fornaro 2014; Benigno, Converse, and Fornaro 2015; Saffie, Varela, and Yi 2020). Few papers have empirically examined the role of CFMs in insulating countries from external shocks in a multi-country setting, but usually treating CFMs as exogenous random variables. Miniane and Rogers (2007) and Bergant et al. (2020), for example, condition the response

of output to external shocks depending on the intensity of CFMs and conclude that CFMs are not effective in insulating output from global shocks. However, it could be argued that not accounting for the endogeneity of CFMs can give rise to treatment bias, as CFMs are likely to be used in response to external and domestic macroeconomic conditions. In this regard, by addressing the inherent endogeneity of CFMs with the use of instrumental variables, Erten and Ocampo (2017) show evidence that the use of CFMs results in a reduction in real exchange rate appreciation.

This paper extends the above empirical analyses on sectoral resource allocations of capital inflows and the insulating role of CFMs by extending the analysis to a larger set of EMDEs and by treating CFMs as an endogenous variable with a PVAR framework. This paper also departs from previous work by focusing on the differentiated response of the real effective exchange rate and tradable output across EMDEs with different degrees of capital account openness (not just comparing the responses of countries with and without CFMs). Also, in contrast to the above empirical research, this paper presents new empirical evidence of Dutch disease-type of effects that could arise from global financial shocks, by focusing on the effects of U.S. monetary policy shocks on currencies and tradable output across a sample that includes the largest and most systemic EMDEs. In this regard, a main contribution of this paper is to empirically show that the severity of financial Dutch disease effects vary almost monotonically with the intensity of the CFMs.

The paper is also related to an extensive Dutch disease literature (see, for example, Magud and Sosa 2013 for a detailed survey). Work in this literature has focused on the reallocation of resources away from the tradable non-commodity sectors, usually as a result of terms-of-trade shocks. The most common friction used to generate the misallocation of resources in response to a currency appreciation is an LBD externality in the tradable sector (see, for example, Van Wijnbergen 1984; Krugman 1987; Caballero and Lorenzoni 2014).

Only in the last decade has there been some development of papers dealing with policy responses to Dutch disease, but focused mainly on terms-of-trade shifts generated by commodity price shocks. Our paper follows closely Lama and Medina (2012), which constructs a New Keynesian model with an explicit commodity exporting sector and an LBD externality in the non-commodity

export sectors to analyze the macroeconomic and welfare effects of exchange rate stabilization policies. Our paper departs from this literature by examining instead Dutch disease effects arising from shocks to global interest rates in a real business cycle model and by examining explicitly the role of CFMs as a policy response.

Finally, the paper contributes to the large literature on the optimality of CFMs as a policy option. This literature has focused mainly on pecuniary externalities associated with financial instability (for this literature see Bianchi 2011 and a survey by Erten, Korinek, and Ocampo 2021) and aggregate demand externalities due to nominal rigidities, associated with unemployment (see Farhi and Werning 2014 and Schmitt-Grohé and Uribe 2016). Recent papers have incorporated these externalities within a framework to analyze the interaction of CFMs with monetary policy, foreign exchange intervention, and macroprudential policy (see Adrian et al. 2020 and Basu et al. 2020). This paper adds to this literature by looking at the merits of CFMs in a DSGE model with frictions in the real sector in the form of costly resource misallocation.

The paper is organized as follows. Section 2 describes the empirical analysis. Section 3 presents the model and the quantitative analysis of the role of CFMs in limiting Dutch disease. Section 4 concludes.

2. Empirics

This section presents empirical evidence on the presence of Dutch disease effects in EMDEs following episodes of sharp reductions in the U.S. policy rate and the usage of CFMs in response to these exogenous shocks. The analysis is based on a PVAR framework with block exogeneity restrictions and variables in the system ordered in recursive order. Data are obtained from publicly available sources for a panel of 25 EMDEs at an annual frequency from 2000 until 2017. Results of the effects of a 1 percentage point reduction in the U.S. policy rate are summarized in the form of cumulative impulse responses at a five-year horizon. To capture the effects of U.S. monetary policy shocks in the post-GFC period and the heterogeneity of responses across countries included in the sample, the coefficients of the PVAR are interacted with a series of country characteristics

(e.g., exchange rate regime or export composition). The PVAR coefficients are also interacted with the different levels of CFMs in order to capture the differentiated response of the REER and tradable output across the different CFM intensity levels.

2.1 Data

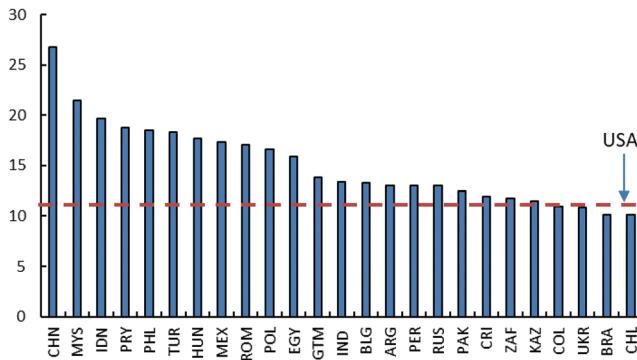

This paper analyzes the effects of a U.S. monetary policy shocks in a sample of 25 EMDEs that have experienced reversals in their paths toward financial account liberalization over the 2000 to 2017 time period.⁶ The sample selection is based on whether a country increased the inflow CFM index at least once during the period of analysis. Also, given that the period of analysis coincided with a boom in oil prices, countries in which oil rents represent more than 15 percent of GDP in the post-GFC period are excluded in order to isolate Dutch disease effects arising from U.S. monetary policy and not a terms-of-trade shock. Finally, low-income countries are excluded, as portfolio inflows (which tend to be more sensitive to global financial conditions) to those economies are generally immaterial. The selected sample represents around 80 percent of total GDP of EMDEs according to the IMF's World Economic Outlook data.

This paper addresses the inherent endogeneity of CFMs by including an index of the intensity of capital controls in the econometric analysis. The index employed, which is one of the few that distinguishes between CFMs on inflows and outflows, is a set of measures on capital control restrictions developed by Fernández et al. (2016). This index uses information from the IMF's Annual Report on Exchange Arrangements and Exchange Restrictions (AREAER). The index provides a unified framework to measure the intensity of inflow CFMs across countries, thereby allowing to compare the use of CFMs in a multi-country setting. In this regard, the empirical section seeks to document that CFMs have been used often across EMDEs in the last two decades.

The variables associated with Dutch disease effects are tradable output and the real exchange rate. For tradable output, the paper

⁶The sample consists of the following economies: Argentina, Brazil, Bulgaria, Chile, China, Colombia, Costa Rica, Egypt, Guatemala, Hungary, India, Indonesia, Kazakhstan, Malaysia, Mexico, Pakistan, Paraguay, Peru, Philippines, Poland, Romania, Russia, South Africa, Turkey, and Ukraine.

Figure 2. Share of Manufacturing Value-Added in GDP in Selected EMDEs, 2019 (in percent)

Source: World Bank, World Development Indicators, and Eurostat.

uses the share of manufacturing value-added in GDP, as this is the most commonly used measure in the Dutch disease literature (Rajan and Subramanian 2011). The data come from the World Bank's World Development Indicators (WDI) database and Eurostat. The importance of manufacturing value-added in GDP varies across EMDEs (Figure 2), with the share of manufacturing in total output being the highest in non-commodity exporting EMDEs (representing around 20 percent of GDP). While capital inflows are the deep determinant of Dutch disease effects, the exchange rate is the proximate transmission mechanism. The paper uses a CPI based real effective exchange rate (REER) obtained from the IMF's Information Notice System.

Finally, the paper uses the Wu and Xia (2016) shadow federal funds rate as a proxy for the U.S. monetary policy rate, which helps to account for periods when the policy rate reached the zero lower bound in the United States after the global financial crisis. The data are for the end of period and obtained from Haver Analytics.

2.2 PVAR Framework

The empirical strategy is based on a PVAR for 25 EMDEs, which seeks to capture the dynamic response of the REER, tradable output, and inflows CFMs to U.S. monetary policy shocks. Simultaneity

issues are addressed in the identification of the empirical model by assuming that countries take innovations in U.S. monetary policy as exogenously given, i.e., variations in the U.S. shadow federal funds rate can be regarded as an exogenous source of aggregate fluctuations in EMDEs. To fix ideas, the PVAR system can be written (abstracting from the intercept) as

$$\begin{aligned} & \begin{pmatrix} 1 & 0 & 0 & 0 \\ a_{i,2,1} & 1 & a_{i,2,3} & a_{i,2,4} \\ a_{i,3,1} & a_{i,3,2} & 1 & a_{i,3,4} \\ a_{i,4,1} & a_{i,4,2} & a_{i,4,3} & 1 \end{pmatrix} \begin{bmatrix} \Delta FFR_t \\ \Delta CFM_{i,t} \\ \Delta REER_{i,t} \\ \Delta Y_{i,t} \end{bmatrix} \\ &= \sum_{j=1}^p A_{i,j} \begin{bmatrix} \Delta FFR_{t-j} \\ \Delta CFM_{i,t-j} \\ \Delta REER_{i,t-j} \\ \Delta Y_{i,t-j} \end{bmatrix} + \begin{bmatrix} \varepsilon_t^1 \\ \varepsilon_{i,t}^2 \\ \varepsilon_{i,t}^3 \\ \varepsilon_{i,t}^4 \end{bmatrix}, \end{aligned} \quad (1)$$

where ΔFFR_t is the one-year change in the Wu and Xia (2016) shadow U.S. federal funds rate, $\Delta CFM_{i,t}$ is the one-year change in CFM index, $\Delta REER_{i,t-j}$ is the log one-year change in the REER, and $\Delta Y_{i,t-j}$ is the log one-year change in the ratio of manufacturing output to total GDP. The lag length is denoted by p . The structural shocks are denoted by $\varepsilon_{i,t}^k$ with $k \in [1, 2, 3, 4]$. The U.S. monetary policy shock is denoted by ε_t^1 .

The exogeneity of U.S. monetary policy and a recursive ordering of the EMDE variables are sufficient assumptions to identify the model. The assumption that monetary policy in the United States does not react to developments in EMDEs identifies $a_{i,2,1}$, $a_{i,3,1}$, and $a_{i,4,1}$. Also, given the block exogeneity assumption, the dynamic effects of U.S. monetary policy shocks will be independent of the ordering of the EMDE variables in the PVAR. The recursive ordering sets $a_{i,2,3} = a_{i,2,4} = a_{i,3,4} = 0$, which amounts to using a Cholesky decomposition of the system. Once these restrictions are imposed and the impact matrix ($A_{i,0}$) is inverted, the structural form of the system specified in Equation (1) above can be written as (again abstracting from country-specific intercepts)

$$Y_{i,t} = \sum_{j=1}^p A_{i,0}^{-1} A_{i,j} Y_{i,t-1} + A_{i,0}^{-1} \varepsilon_{i,t}, \quad (2)$$

where $Y_{i,t} = [\Delta FFR_t \ \Delta CFM_{i,t} \ \Delta REER_{i,t} \ \Delta Y_{i,t}]'$. This can be written more compactly in companion matrix form as a VAR(1) by defining $Z_{i,t} = [y_{i,t} : y_{i,t-1} : \dots : y_{i,t-p}]'$,

$$Z_{i,t} = \Lambda_i Z_{i,t-1} + A_{i,0}^{-1} \varepsilon_{i,t},$$

$$\text{where } \Lambda = \begin{bmatrix} A_{i,0}^{-1} A_{i,1} & A_{i,0}^{-1} A_{i,2} & \dots & A_{i,0}^{-1} A_{i,p} \\ I & 0 & \dots & 0 \\ 0 & I & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \dots & I & 0 \end{bmatrix}.$$

The impulse response for variable k to a U.S. monetary policy shock at horizon $h = 1, \dots, H$ is denoted by

$$IRF_k(1, h) = \Lambda_i^{h-1} A_{i,0}^{-1}(k, 1). \quad (3)$$

That is, the impulse response of the variable k to a U.S. monetary policy shock will be in the k^{th} row and first column, for $h = 1, \dots, H$.⁷

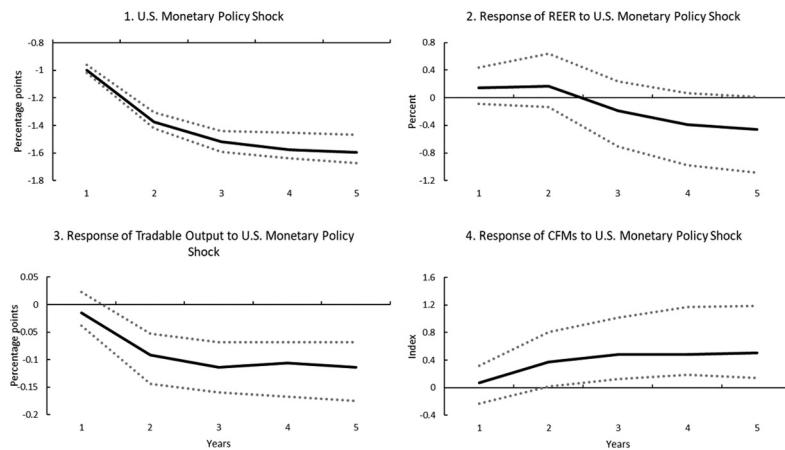

Each equation of the system is estimated using ordinary least squares (OLS), with two lags following the Schwartz criterion. Statistical inference is based on Runkle's (1987) bootstrapping method to adjust for the fact that the data are in a panel format. This procedure consists of the following steps:

- (i) Estimate the PVAR(p) in Equation (2) and generate 500 bootstrap replications of the coefficient matrix \hat{A}_i .⁸
- (ii) Impulse response functions (IRFs) are computed 500 times for each generated variable k^* to the first structural shock (that is the U.S. monetary policy shock) at horizon $h = 1, \dots, H$.

⁷This representation also requires augmenting both the $A_{i,0}^{-1}$ and $\varepsilon_{i,t}$ with $(k+1) \times p$ rows or columns of zeros for the matrix multiplication to work, given the dimension of $Z_{i,t}$, which is $(p+1) \times (k+1)$.

⁸Bootstrapping for the panel was done by generating initial conditions separately for each country as in Runkle (1987), but sampling from the entire panel vector of residuals. This was done to account for possible cross-country correlations.

Figure 3. Effects of U.S. Monetary Policy Shocks on EMDEs

Note: Solid black lines represent OLS point estimate. Dashed lines are one-standard-deviation confidence bands.

- (iii) Finally, the bootstrap simulations are used to calculate the empirical distribution for the IRFs. One-standard-deviation confidence intervals are constructed from the simulated estimates using the structural errors and without imposing symmetry in the confidence bands.

2.3 Results

Figure 3 shows the impulse responses to a 1 percentage point reduction in the U.S. monetary policy rate obtained from estimating the PVAR using a sample of 25 EMDEs from 2000 to 2017. Solid lines represent the OLS point estimates while dotted gray lines are one-standard-deviation confidence bands constructed using the empirical distribution obtained from the bootstrap procedure. Reflecting the unprecedented scale of monetary policy support in the United States following the global financial crisis, there is a protracted decline in the U.S. shadow policy rate following the initial, reaching a cumulative decline of 1.6 percentage points in the five-year horizon window (Figure 3, panel 1). Consistent with the empirical evidence on the behavior of EMDEs' currencies in the last two decades, the real

effective exchange rate appreciated on the year of the U.S. monetary policy shock, but this appreciation is not statistically significant and reverted after the second year (Figure 3, panel 2).⁹

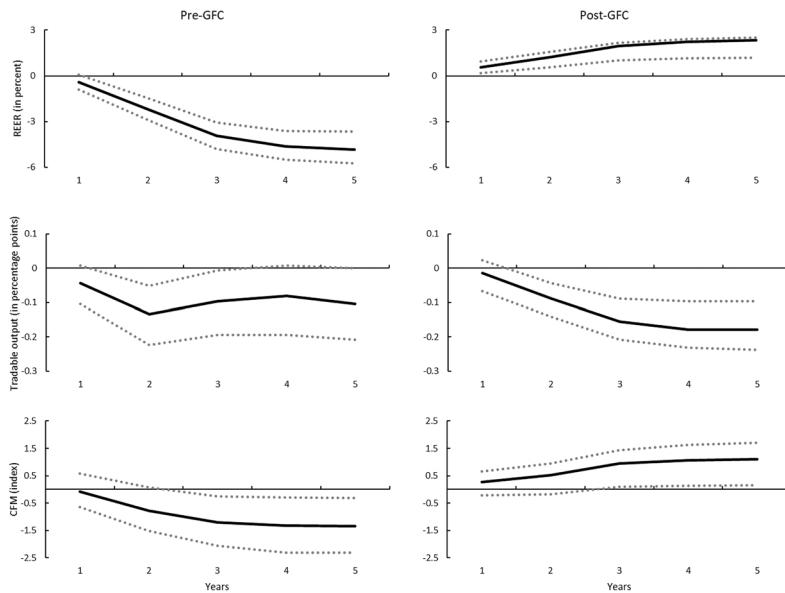

The strengthening of the currency, summarized in the REER response, coincided with a reallocation of resources across sectors in these economies. Figure 3 (panel 3) shows the response of the share of manufacturing value-added in GDP. The U.S. monetary policy shock and the ensuing currency appreciation in EMDEs coincides with a contraction in the share of manufacturing production. The contraction of tradable output is also relatively long-lasting throughout the IRF five-year horizon. This result is consistent with the findings of Rajan and Subramanian (2011), who document that in episodes of surges of foreign capital (in the form of aid) to EMDEs, exportable industries grow slower by about half a percentage point per year relative to non-exportable industries. In terms of policy response, following the U.S. monetary policy shocks, it was also common to see a tightening of CFMs on inflows in the sample of 25 EMDEs (Figure 3, panel 4). All in all, these results suggest that Dutch disease effects were common among EMDEs as a result of large shifts in global financial conditions.

2.3.1 Extensions

As shown in Figure 1, the unprecedented U.S. monetary policy response in the aftermath of the GFC coincided with a surge in capital inflows, currency appreciation, and widespread use of CFMs on inflows across EMDEs. By extending the baseline analysis, this section looks into whether the presence of Dutch disease effects and the use of CFMs was in fact more common in the post-GFC period. The section also examines whether the occurrence of Dutch disease effects varied with exchange rate regimes, across income levels, and the primary source of export earnings. These extensions are going to be incorporated to the baseline analysis described by allowing

⁹The lack of a significant REER response could be explained by the fact that the loosening of U.S. monetary policy in the early 2000s coincided with severe financial crises in systemic EMDEs (e.g., Argentina, Turkey). Therefore, the appetite for EM assets was likely lower than post-GFC. In fact, as will be shown later in the paper, Dutch disease effects are much more evident in the post-GFC period.

Figure 4. Effects of U.S. Monetary Policy Shocks on EMDEs, Pre- and Post-GFC

Note: Solid black lines represent OLS point estimate. Dashed lines are one-standard-deviation confidence bands.

the coefficients in the $A_{i,j}$ matrix described in Equation (2) to vary across pre- and post-GFC and with country characteristics:¹⁰

$$A_{i,j} = \beta_{i,j} + \varsigma_{i,j} * Characteristic_{i,t}. \quad (4)$$

As a first step, the PVAR coefficients in Equation (1) are interacted with a post-GFC dummy variable that equals one from 2008 until 2017 and zero otherwise.

The results presented in Figure 4 confirm that Dutch disease effects and the use of CFMs were common in EMDEs as a result of U.S. monetary policy shocks in the aftermath of the GFC. Before the GFC, expansionary U.S. monetary policy shocks led to weaker currencies, and the effect of the shock on tradable output was somewhat

¹⁰See Towbin and Weber (2013) for a discussion of PVARs with interaction terms.

limited (left panels).¹¹ Many of these economies also reduced the number of CFM restrictions following the U.S. shock. On the other hand, looser U.S. monetary policy after the GFC resulted in significant currency appreciation, with the effect of U.S. shocks having a protracted effect on the REER (right panels). These changes in relative prices led to a significant reduction in tradable output, confirming the presence of Dutch disease. As in the baseline case, EMDEs typically responded to these events by imposing additional restrictions on the capital account.

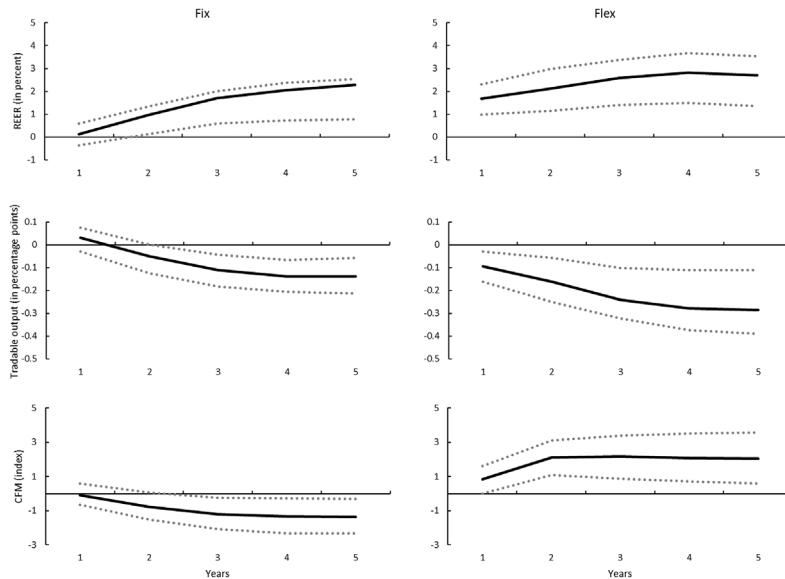

The different reactions pre- and post-GFC may not be the result of differences in the effects of U.S. monetary policy, but instead of changes in exchange rate policies in EMDEs. Recent empirical work has documented that movements in currencies following external shocks depend on the degree of exchange rate flexibility (see Carrière-Swallow, Magud, and Yépez 2021). At the same time, economies under a fixed exchange rate regime are likely to already have extensive currency controls, hence the scope to add an additional restriction is more limited. In order to test these hypotheses, the baseline analysis is also extended to assess whether the occurrence of Dutch disease and the use of CFMs in the aftermath of the GFC depended on the degree of exchange rate flexibility. To do this, the PVAR coefficients are also interacted with a dummy equal to one if the EMDE has a peg (“fix”) and zero for non-peg (“flex”). The exchange rate classification is from Ilzetzki, Reinhart, and Rogoff (2017).

The results presented in Figure 5 confirm that indeed Dutch disease effects were more common in the post-GFC among EMDEs with a more flexible exchange rate regime (right panels). Following an expansionary U.S. monetary policy shock, currencies appreciated and the share of manufacturing value-added in GDP declined in significantly larger magnitudes in EMDEs with more flexible exchange rate regimes. In these economies the larger presence of Dutch disease coincided also with the imposition of additional restrictions on capital inflows.

A number of papers have documented that global financial conditions appear to drive capital flows to EMDEs even more so than for

¹¹This explains the lack of a significant REER response when the PVAR uses the 2000–17 sample period.

Figure 5. Effects of U.S. Monetary Policy Shocks on EMDEs, by Exchange Rate Regime

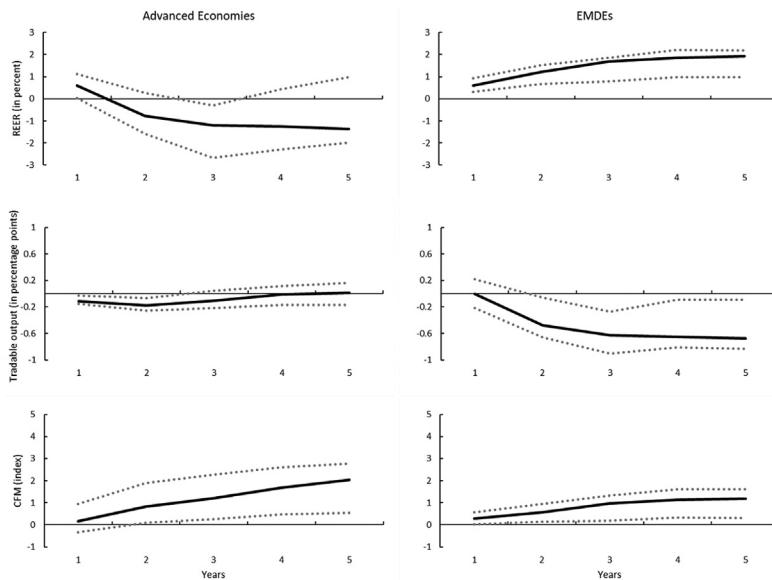

Note: Solid black lines represent OLS point estimate. Dashed lines are one-standard-deviation confidence bands.

AEs (see, for example, Forbes and Warnock 2012; Fratzscher 2012). Given the larger presence of currency mismatches and lower policy credibility, policies aimed at stabilizing the exchange rate are more likely to be deployed in EMDEs than in AEs (see Rogoff et al. 2004). In this regard it could be expected that the use of CFMs to be more common in EMDEs than in AEs.

To shed light on the differences between EMDEs and AEs, the sample is expanded to include nine AEs. The selection criteria for AEs was similar to the baseline sample, mainly that there was at least one increase in the annual CFM index during the period of analysis.¹² Impulse responses are constructed by interacting the

¹²The AEs included are Canada, Czech Republic, euro area, Iceland, Israel, Korea, Norway, Singapore, and Sweden. Euro area countries are not individually included, since it is not possible to consider these economies as independent cross-sectional observations.

Figure 6. Effects of U.S. Monetary Policy Shocks on EMDEs, by Income Group

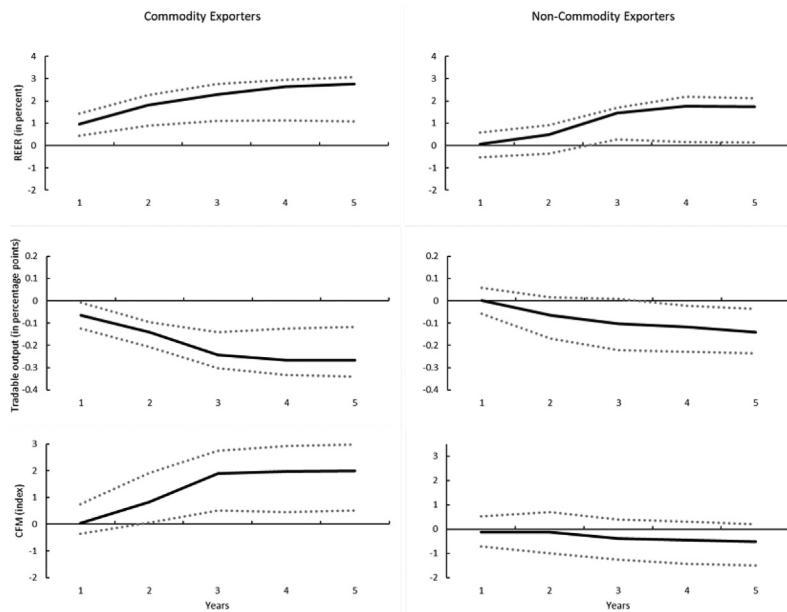

Note: Solid black lines represent OLS point estimate. Dashed lines are one-standard-deviation confidence bands.

PVAR coefficients with a dummy variable that equal one if a country is an EMDE and zero if AE, focusing only in the post-GFC period.

The results suggest that Dutch disease following U.S. monetary policy shocks in the post-GFC occurred mainly in EMDEs (Figure 6). For AEs (left panel), the currency depreciates following the shock, albeit not in a statistically significant way. The weaker currency helped to stimulate tradable output, with the share of manufacturing value-added in GDP increasing somewhat at the end of the IRF horizon. Interestingly, AEs also made use of CFMs.

Anzuini, Lombardi, and Pagano (2013) present evidence that expansionary U.S. monetary policy shocks tend to drive up commodity prices. Since the post-GFC period was characterized by boom-bust cycle of commodity prices, it would be important to test whether the prevalence of Dutch disease effects and the use of CFMs differs across EMDEs depend on export composition. Impulse

Figure 7. Effects of U.S. Monetary Policy Shocks on EMDEs, by Export Composition

Note: Solid black lines represent OLS point estimate. Dashed lines are one-standard-deviation confidence bands. A country is classified as a commodity exporter following Aslam et al. (2016) criteria. Commodity exporters: Argentina, Brazil, Chile, Colombia, Costa Rica, Guatemala, Indonesia, Kazakhstan, Malaysia, Peru, Paraguay, and Russia.

responses are constructed by interacting the PVAR coefficients with a dummy variable that equals one if a country is classified as a commodity exporter and zero otherwise.¹³

Results presented in Figure 7 show that U.S. monetary policy shocks in the post-GFC period gave rise to Dutch disease effects

¹³The classification uses Aslam et al. (2016). A country is classified as a commodity exporter if (i) commodities constitute at least 35 percent of its total exports and (ii) net exports of commodities are at least 5 percent of its gross trade (exports plus imports) on average. Based on this criteria, the following EMDEs are classified as commodity exporters: Argentina, Brazil, Chile, Colombia, Costa Rica, Guatemala, Indonesia, Kazakhstan, Malaysia, Peru, Paraguay, and Russia.

in commodity and non-commodity exporting EMDEs. Following a 1 percentage point reduction in the U.S. shadow federal funds rate, currencies appreciate and the share of tradable output in total output declines in commodity and non-commodity exporting EMDEs. Furthermore, these effects are larger for commodity exporting EMDEs, in line with previous findings that commodity prices are an important transmission channel for spillovers arising from U.S. monetary policy shocks (see, for example, Anzui, Lombardi, and Pagano 2013 and the references therein). More importantly, commodity exporters responded to the U.S. monetary policy shock by tightening CFMs, a sign that the higher capital inflows were a key factor behind the emergence of Dutch disease in these economies. The CFM response for non-commodity exporting EMDEs is not significant.

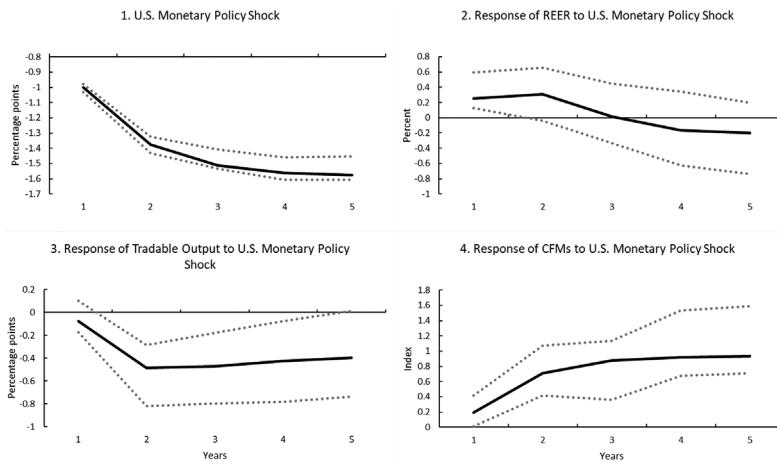

2.3.2 Robustness

As a first robustness exercise, the paper looks at whether similar findings occur if a different CFM index is used. The alternative CFM measure used is the one provided by Chinn and Ito (2008). This measure is publicly available, provides the largest country coverage, and is constructed at an annual frequency. Figure 8 shows that U.S. monetary policy shocks after the GFC also led to an increase in the Chinn and Ito (2008) index. Also as observed in the baseline estimation and subsequent extensions, the U.S. monetary shock leads to significant Dutch disease effects in the post-GFC period. Although similar results are obtained using this alternative index, the use of the index provided by Fernández et al. (2016) is preferred as a baseline, given that the index differentiates between restriction on inflows and outflows and focuses only on capital account transactions.¹⁴

As another robustness check to the empirical analysis, the paper looks at whether Dutch disease effects in EMDEs are also evident when using a different measure of U.S. monetary policy shocks. Jarociński and Karadi (2020) use unexpected changes in federal

¹⁴The Chinn and Ito (2008) index also captures restrictions on current account transactions.

Figure 8. Effects of U.S. Monetary Policy Shocks on EMDEs, Using Chinn and Ito (2008) CFM Index

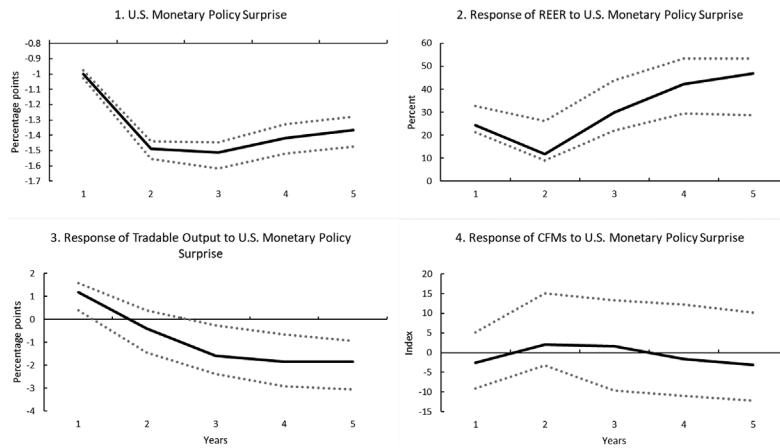

Note: Solid black lines represent OLS point estimate. Dashed lines are one-standard-deviation confidence bands.

funds rate and Eurodollar futures on Federal Open Market Committee (FOMC) dates to measure policy surprises. Using a high-frequency identification strategy, they can rule out the simultaneity of economic news and monetary policy. In this paper, the U.S. monetary policy surprises are accumulated within a year and used to estimate causal effects running from U.S. monetary policy shocks to the REER, tradable output, and CFMs in EMDEs.

Dutch disease effects in EMDEs are also evident following expansionary U.S. monetary policy surprises (Figure 9). An unanticipated loosening in U.S. monetary policy leads to a multilateral real appreciation of currencies on the year after the shock, and a subsequent protracted contraction in the share of manufacturing in GDP. As in the baseline, EMDEs respond by tightening CFMs, although the IRF is somewhat noisier and less precise.

Hildebrandt and Michaelis (2022), by introducing physical capital to the production technology in Benigno and Fornaro (2014), show that an investment surge resulting from more accommodative global interest rates could prevent a contraction in the tradable sector. Against this backdrop, and as a final robustness test,

Figure 9. Effects of U.S. Monetary Policy Surprises on EMDEs

Note: Solid black lines represent OLS point estimate. Dashed lines are one-standard-deviation confidence bands.

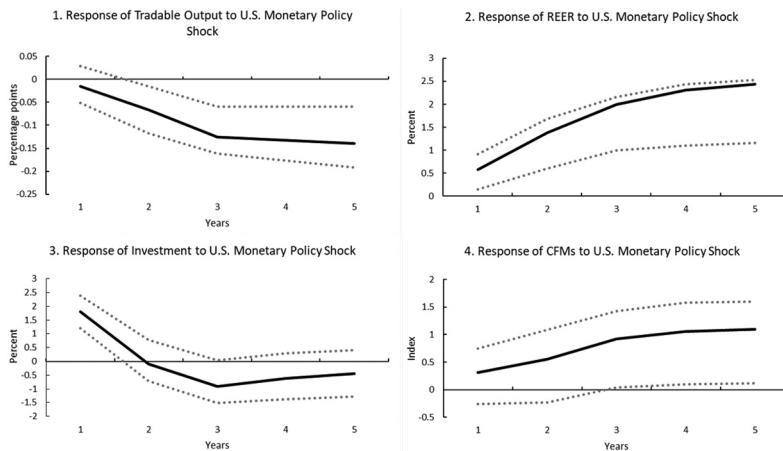

the baseline PVAR specification in Equation (1) is augmented to include real investment growth as an additional variable in order to assess whether Dutch disease occurs even after controlling for investment dynamics.¹⁵ Results presented in Figure 10 show that investment indeed increased as a result of the U.S. monetary policy shock across EMDEs, but the increase is somewhat short-lived and does not prevent a reallocation away from the tradable sector. Also, even after controlling for investment dynamics, the real exchange rate shows a significant and protracted appreciation and this response is accompanied by a tightening in CFMs.

2.3.3 Assessing the Effectiveness of CFMs

Given the results presented above, and as a way of motivation for the next section, a natural question is to ask whether the use of CFMs

¹⁵Real investment is obtained from the World Bank's WDI database (i.e., gross capital formation in constant local-currency units). This variable enters the PVAR in log first differences. Given the block exogeneity assumption regarding the shadow U.S. federal funds rate in the PVAR specification, the ordering of investment in the EMDE block is immaterial.

Figure 10. Effects of U.S. Monetary Policy Shocks on EMDEs, Controlling for Investment

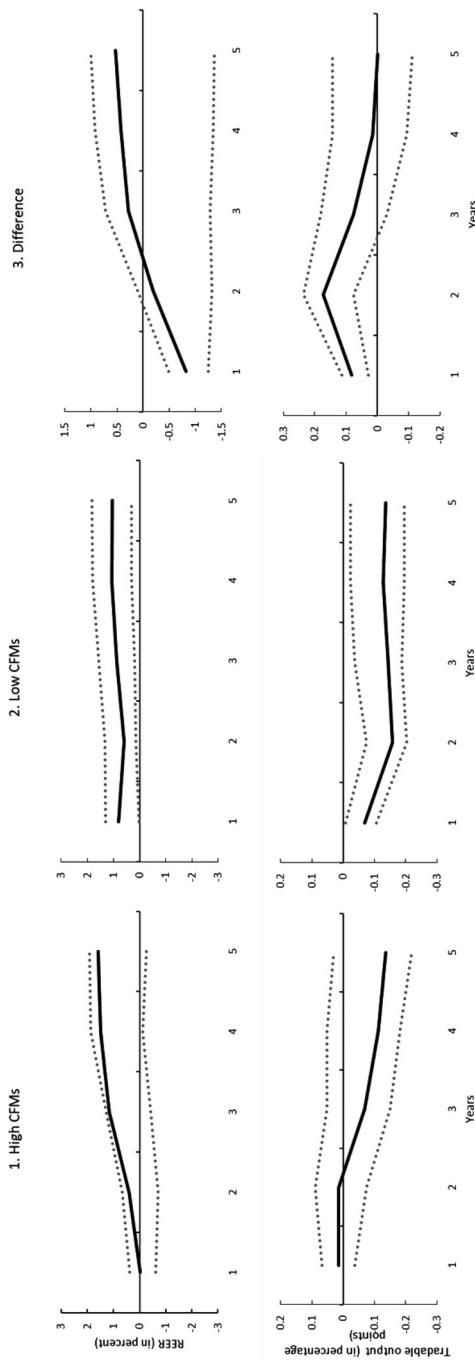

Note: Solid black lines represent OLS point estimate. Dashed lines are one-standard-deviation confidence bands.

helps EMDEs in attenuating Dutch disease effects during periods of ultra-accommodative monetary policy in the United States, such as in the aftermath of the GFC. To answer this question, the baseline PVAR specification described in Equation (1) is modified by excluding the CFM variable from the system of equations, but allowing the coefficients in the $A_{i,j}$ matrices to vary with the level of the CFM index. This exercise aims at capturing the differentiated effect of U.S. monetary policy shocks on EMDEs after the GFC, depending on the intensity of CFMs.

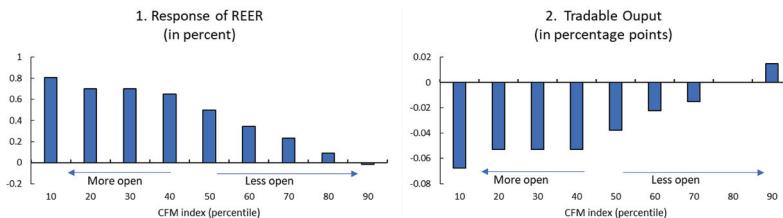

Results indeed show a differentiated response of the REER and tradable output across the different levels of CFMs on inflows. In EMDEs with a lower level of CFMs (a more open capital account), the real exchange rate appreciates and the share of tradable output in total output declines significantly after impact (see panel 2 in Figure 11). On the other hand, for EMDEs with a higher CFM index (a less open capital account), there are no significant effects on the REER and tradable output (see panel 1 in Figure 11). Furthermore, the differences in the responses between the two groups is statistically significant in the first two years after impact (see panel 3 in

Figure 11. Effects of U.S. Monetary Policy Shocks, by CFM Level

Note: Solid black lines represent OLS point estimate. Dashed lines are one-standard-deviation confidence bands. “High CFMs” refer to 90th percentile, while “Low CFMs” refer to the 10th percentile of the sample distribution.

Figure 12. Effects of U.S. Monetary Policy Shocks, Over Distribution of CFM Index

Note: Each bar represents the impulse response on impact of a 1 percent reduction in the U.S. federal funds rate, evaluated at a given percentile of the sample distribution of the CFM index.

Figure 11). These results are in line with Rodrick (2008) and Erten and Ocampo (2017), who also present evidence that the use of CFMs limits currency appreciation.

Results can be generalized to the full sample distribution of the CFM index. The effect of the U.S. monetary policy shock on the REER and tradable output is estimated at different values of the CFM index. Figure 12 shows an almost monotonic relationship between the openness of the capital account and the response of the REER, which is a key finding of this paper. While currencies in EMDEs with the most open capital accounts appreciate markedly on impact, currencies in the less open capital account regimes are less affected by the shock. However, as shown in the results presented in previous sections, CFMs tend to increase in response to foreign financial shocks across EMDEs; therefore, there may be reverse causality as countries with greater currency appreciation may attract more capital inflows, which may trigger the use of more restrictive CFMs.¹⁶

Given the endogeneity of CFMs and possible reverse-causality issues with this empirical approach, it is crucial to use a structural framework to uncover the systematic effect of CFMs. Equation (1) helps to illustrate how one could conceptually analyze how U.S. monetary policy shocks affect the REER (i.e., the transmission mechanism). There is a contemporaneous effect through coefficient $a_{i,3,1}$,

¹⁶Results are unchanged if the PVAR coefficients are interacted with the one-year lagged CFM index.

and dynamically through the relevant coefficients in the $A_{i,j}$ matrices. But there are also indirect effects of U.S. monetary policy shocks to the extent that these shocks lead to more CFMs contemporaneously (through $a_{i,2,1}$) and in turn CFMs affect the REER (through $a_{i,3,2}$). Moreover, CFMs can insulate EMDEs from U.S. monetary policy shocks if they respond to these shocks at any horizon and the coefficients for lagged values of CFMs in the REER and output equations are significant.

However, the coefficients in the PVAR are not “deep” parameters, as these are not based on micro-foundations, which limits the use of the PVAR to perform a counterfactual analysis of what would have happened if there was no CFM response (i.e., the coefficients for the CFM variable are set to zero in Equation (1)). As explained in Lucas (1976), there is the possibility that if the process followed by the policy of implementing CFMs differed from the historical pattern, other equations of the system might have behaved differently as well. Therefore, a structural model, with micro-founded parameters, is needed in order to evaluate the effectiveness and appropriateness of CFMs in limiting Dutch disease. The paper develops this model in the next section.

3. The Theoretical Model

A dynamic stochastic general equilibrium (DSGE) model is developed in order to qualitatively match the empirical findings presented in the previous section. The model is similar to Arellano (2009). It uses a small open economy assumption and consists of a representative household and two industries (tradable and non-tradable). Households have restricted access to international credit markets, as there is a tax on foreign debt (i.e., a CFM).

In order to justify the use of CFMs, the model includes an externality in the production technology of tradable goods. The externality is a learning-by-doing (LBD) mechanism and is incorporated along the lines of Cooper and Johri (2002). Firms in the tradable sector do not take into account the LBD process in their production process. Since the planner solution internalizes this process in the production of tradables, this sector will face increasing returns to scale on the aggregate level, while constant returns to scale technology at the firm level as in Romer (1986). This externality produces

an inefficient allocation of resources following a shock to the global interest rate.

3.1 Households

Households in the economy maximize their expected lifetime utility and have preferences over consumption and leisure:

$$U = E_0 \sum_{t=0}^{\infty} \beta^t \frac{\left(c_t^\omega (1 - h_t)^{1-\omega}\right)^{1-\gamma} - 1}{1 - \gamma}. \quad (5)$$

β is a subjective discount factor. Household consumption, c_t , consists of non-tradable consumption $c_{N,t}$, and tradable consumption $c_{T,t}$, and has a constant elasticity of substitution form:

$$c_t = \left[\varphi (c_{T,t})^{-\mu} + (1 - \varphi) (c_{N,t})^{-\mu} \right]^{-\frac{1}{\mu}}.$$

Labor, h_t , is allowed to move freely between the two sectors ($h_t = h_T + h_N$), making the wage households receive the same in both sectors.

The flow budget constraint, in tradable good terms, is as follows:

$$\begin{aligned} B_t &= (1 + r_{t-1}^d) B_{t-1} - w_t h_t - r_t^k k_t - T_t - \Pi_t^f \\ &\quad + p_{N,t} c_{N,t} + c_{T,t} + i_t + \frac{\kappa}{2} (B_t - \bar{B})^2. \end{aligned} \quad (6)$$

B_t denotes the household's foreign debt position, $p_{N,t}$ is the relative price of non-tradables in terms of tradables (equivalent to the real exchange rate), k_t is capital, and i_t is investment.¹⁷

$\frac{\kappa}{2} (B_t - \bar{B})^2$ is the cost of adjusting the country's foreign debt position. Following Schmitt-Grohé and Uribe (2003), the model introduces these adjustment costs with the sole purpose of eliminating the familiar unit root built in the dynamics of standard formulations of the small open economy model. As discussed in Uribe and Yue (2006), the debt adjustment cost can be decentralized as a bank operational cost.

¹⁷Investment is in tradables only.

T_t denotes government lump-sum transfers, and Π_t^f are dividends received from firms. The interest rate at which the households can borrow from international markets is given by

$$r_t^d = (1 + \tau(B_t)) \exp(-\eta_t) r^*.$$

$\tau(B_t)$ denotes taxes on foreign debt interest rate payments and has the following functional form (as in Kitano 2011):

$$\tau(B_t) = \frac{\tau}{2} (B_t - \bar{B})^2,$$

where τ is a parameter representing the intensity of the tax, and \bar{B} denotes the economy's steady-state foreign debt position.¹⁸ Foreign debt interest rate payments are based on the world interest rate r^* , which is exogenously determined, and subject to a random disturbance term denoted by η_t . Finally, r_t^k is the rental rate of capital and w_t is the real wage. The process of capital accumulation is given by

$$k_{t+1} = (1 - \delta) k_t + i_t - \frac{\phi}{2} \left(\frac{k_{t+1} - k_t}{k_t} \right)^2, \quad (7)$$

where $\frac{\phi}{2} \left(\frac{k_{t+1} - k_t}{k_t} \right)^2$ represents a capital adjustment cost.

Optimality conditions for consumption, labor, foreign debt, and capital are

$$\frac{1 - \varphi}{\varphi} \left(\frac{c_{N,t}}{c_{T,t}} \right)^{-(\mu+1)} = p_{N,t}, \quad (8)$$

$$\frac{\omega}{1 - \omega} \frac{1 - h_t}{c_t} = \frac{p_{N,t}}{w_t}, \quad (9)$$

$$\begin{aligned} & -\lambda_t \left(1 - \kappa \left(\frac{B_t - \bar{B}}{\bar{B}} \right) \right) \\ & + \beta^t (1 + \exp(-\eta_t) r^* (1 + \tau(B_t) + \tau'(B_t) B_t)) E_t [\lambda_{t+1}] = 0, \end{aligned} \quad (10)$$

¹⁸ \bar{B} is calibrated to equal to zero in steady state, thus tax revenues are on the full stock of foreign debt.

and

$$\begin{aligned} & -\lambda_t [1 + \phi(k_{t+1} - k_t)] \\ & + \beta^t E_t [\lambda_{t+1} (1 + r_{t+1}^k - \delta + \phi(k_{t+2} - k_{t+1}))] = 0. \end{aligned} \quad (11)$$

The marginal utility of consumption is denoted by

$$\lambda_t = \omega c_t^{\omega(1-\gamma)-1} (1 - h_t)^{(1-\omega)(1-\gamma)}.$$

3.2 Firms

There are two sectors in this economy: tradable and non-tradable. Firms in both sectors are competitive. Following the Dutch disease literature (see Lama and Medina 2012 and the discussion therein), the production of tradables in this economy is subject to an LBD externality. Firms in this sector choose labor and capital to maximize profits, and produce output according to a Cobb-Douglas production function:

$$Y_{T,t} = A_{T,t} l_t^\xi k_t^\alpha h_{T,t}^{1-\alpha}. \quad (12)$$

$A_{T,t}$, k_t , and $h_{T,t}$ denote an exogenous productivity shock, capital, and labor, respectively, with both α and ξ between zero and one. Average organizational capital in the production of tradables is denoted by l_t , and is specified as in Cooper and Johri (2002):

$$l_{t+1} = l_t^\zeta Y_{T,t}^\psi, \quad (13)$$

with $\zeta + \psi = 1$. The rationale behind this LBD mechanism is that production in the tradable sector increases the experience of workers, and this further improves productivity in the future. As in Romer (1986), individual firms assume that they cannot affect the aggregate stock of organizational capital, so they take l_t as given. This makes firms infer that they are facing a constant returns to scale technology, making the problem of the firm quite standard. On the other hand, a social planner would observe that (12) is an increasing return to scale technology at the aggregate level, therefore considering the effect of the LBD mechanism in production via the experience gained. This externality can be viewed as a moving cost from the

tradable to the non-tradable sector, and if this cost is not internalized by firms, it will have considerable implications for the economy's aggregate welfare levels.

Firms in the non-tradable sector produce output with a simple technology that is linear in labor and is described by

$$Y_{N,t} = A_{N,t} h_{N,t},$$

where $A_{N,t}$ is a sector-specific exogenous productivity shock. Labor is perfectly mobile across sectors. Firms in the two sectors obtain their inputs for production from the household, so that in equilibrium the wage rate equals the marginal productivity of labor and the rate of return on capital equals the marginal productivity of capital. Since in equilibrium marginal productivity of labor across sectors are equalized, leading to

$$w_t = (1 - \alpha) \frac{Y_{T,t}}{h_{T,t}} = p_{N,t} \frac{Y_{N,t}}{h_{N,t}}. \quad (14)$$

Finally, the optimality condition for capital is

$$r_t^k = \alpha \frac{Y_{T,t}}{k_{T,t}}. \quad (15)$$

3.3 Government

For simplicity, it is assumed that the government runs a balanced budget. Its revenue, the CFM tax, is rebated back to households as lump-sum transfers,

$$T_t = \tau(B_t) \exp(-\eta_t) r^* B_t.$$

3.4 Equilibrium

The market clearing conditions for labor and the two production sectors are

$$h_t = h_{T,t} + h_{N,t}$$

$$Y_{N,t} = c_{N,t}$$

$$Y_{T,t} = c_{T,t} + i_t.$$

The competitive equilibrium of this model is defined as the state-contingent sequences of allocations and prices

$$\{c_{N,t}, c_{T,t}, k_{t+1}, h_t, h_{N,t}, h_{T,t}, p_{N,t}, B_t, r_t^k, w_t\}_{t=0}^{\infty},$$

such that (i) households maximize expected utility subject to their budget and time constraints taking prices as given, (ii) firms maximize profits subject to their technology taking input prices as given, and (iii) markets clear.

3.5 Parameterization

The parameters used to solve and simulate the model are listed in Table 1. The time frequency is supposed to be quarterly. All of the parameters with the exception of tradable production technology are obtained from similar studies of small open economies and are typical parameters used in the real business cycle literature. The parameters for the tradable production are obtained from Cooper and Johri (2002), which estimates parameters for Equations (12) and (13) simultaneously using two-digit manufacturing data for the United States. In order to fully identify the parameters of the system, some restrictions have to be imposed. For the purpose of this paper, the parameters used correspond to the Cooper and Johri (2002) estimation assuming increasing returns to scale in the production function.¹⁹

The parameter for the foreign debt adjustment cost is the smallest possible value close to zero, so that any effect on domestic interest rates is primarily driven by debt levels and capital controls.²⁰ The model is solved numerically by taking log-linear approximations of the equilibrium conditions around the steady state.

This chapter assumes that the processes for the shocks affecting the economy are

$$\ln(A_{T,t}) = 0.95 \ln(A_{T,t-1}) + \epsilon_{T,t}, \epsilon_{T,t} \sim N(0, \sigma_T^2), \sigma_T = 0.007, \quad (16)$$

¹⁹It is worth noting that from all their identification methods, assuming increasing returns to scale is the only one that produces all estimates of production parameters to be significantly different from zero.

²⁰This parameter cannot be set equal to zero, since bond holding costs are necessary to ensure bond holdings do not display a unit root (Schmitt-Grohé and Uribe 2003).

Table 1. Parameterization

Parameter	Symbol	Value	Source
Foreign Interest Rate	r^*	0.02	Standard
Share of Tradables in Consumption	φ	0.45	Uribe and Yue (2006)
Subjective Discount Factor	β	0.98	
Inv. Elast. of Intertemp. Sub.	γ	2	Acosta, Lartey, and Mandelman (2009)
Elast. of Sub., Consumption	ω	0.22	Acosta, Lartey, and Mandelman (2009)
Elast. of Sub., Tradables	μ	0.316	Acosta, Lartey, and Mandelman (2009)
Foreign Debt Adjustment Cost	κ	0.0003	Author
Parameter for Investment Adj. Cost	ϕ	2.2	Acosta, Laney, and Mandelman (2009)
Capital Share	α	0.33	Cooper and Johri (2002)
Labor Share, Tradable Sector	Φ	0.67	Cooper and Johri (2002)
Learning Rate	ξ	0.26	Cooper and Johri (2002)
Output Elasticity, Org. Capital	ψ	0.5	Cooper and Johri (2002)
Depreciation Rate, Org. Capital	ζ	0.5	Cooper and Johri (2002)
Depreciation Rate	δ	0.025	Lama and Medina (2012)

$$\begin{aligned} \ln(A_{N,t}) &= 0.95\ln(A_{N,t-1}) \\ &+ \epsilon_{N,t}, \epsilon_{N,t} \sim N(0, \sigma_N^2), \sigma_N = 0.0035, \end{aligned} \quad (17)$$

and

$$\eta_t = 0.98\eta_{t-1} + \epsilon_{\eta,t}, \epsilon_{\eta,t} \sim N(0, \sigma_\eta^2), \sigma_\eta = 0.01. \quad (18)$$

The persistence parameters and the standard deviations for the technology in both sectors are obtained from Lartey (2008). Given the quarterly frequency of the model, the parameters for the foreign interest rate are estimated using the U.S. three-month Treasury-bill rate.

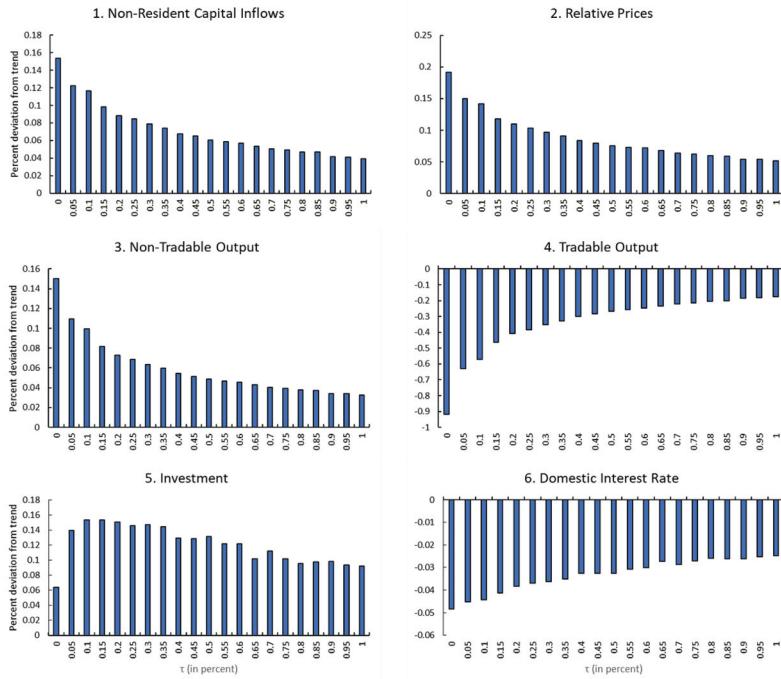

3.6 Model Simulations

This subsection presents the impulse response functions (IRFs) from the model simulations to a two-standard-deviation reduction in the world interest rate. The IRFs show the effect one year (i.e., four quarters) after impact. In order to illustrate the endogenous effect of CFMs in insulating the economy from a global interest rate shock, simulations are run for different levels of the tax on foreign interest rate payments (τ).

Results show that a (negative) two-standard-deviation shock to the world interest rate increases net foreign borrowing (Figure 13, panel 1), which in turn leads to higher consumption of both tradables and non-tradables. The higher demand for non-tradables increases wages and the relative price of non-tradables (Figure 13, panel 2), causing labor to reallocate from the tradable to the non-tradable sector (Figure 13, panel 3). This reallocation of labor causes a contraction of output in the tradable sector (Figure 13, panel 4). The reduction in the global interest rate passes through to domestic interest rates and investment increases (Figure 13, panels 5 and 6). All in all, the model does a good job of capturing Dutch disease effects in response to the increased availability of foreign-financed tradable goods.

This theoretical simulation allows the analysis to isolate the role of CFMs. As shown in Figure 13, by curving the availability of foreign capital, the tax on foreign debt payments (i.e., the CFM) limits the rise in relative prices (i.e., an appreciation of the currency) and

**Figure 13. Theoretical Impulse Responses
to Global Interest Rate Shocks**

Note: Each bar corresponds to the one-year response to a two-standard-deviation reduction in the global interest rate shock for different CFM (τ) rates.

the ensuing contraction in the tradable output. While it is clear from examining Equation (12) that the initial contraction in the tradable sector will be exacerbated by a reduction in the level of organizational capital, it is not evident that limiting this contraction would be optimal from the social planner's point of view. Increasing the cost of foreign capital by too much slows the economy's investment rate. Furthermore, some reallocation from tradable to non-tradable sectors would still be an efficient response to the reduction in the global interest rate.

In terms of positive implications, the impulse responses in the structural model are symmetric. Hence an increase in the global interest rate will lead to a reduction in relative prices and a reallocation of resources from the non-tradable to the tradable sector.

However, in the model the reallocation of resources from the non-tradable to the tradable sector is “costless,” hence the optimality of CFMs would not depend on the direction of the shock to the global interest rate. Therefore, as explained in the next section, the optimality of CFMs in this economy is assessed against the ability of these policy instruments in allowing the most efficient reallocation of resources across sectors.

3.7 Welfare Analysis

The welfare analysis is based on Schmitt-Grohé and Uribe (2004), and it calculates the fraction of consumption required for households in an economy with no CFMs to be as well off as households in an economy with CFMs. This welfare value is calculated for different CFM levels, represented by τ in the model, in order to identify the CFM rate that maximizes household’s expected lifetime utility. The economy with no CFMs ($\tau = 0$) will be denoted by B, and will be considered the benchmark model. On the other hand, the economy with CFMs ($\tau > 0$) will be denoted by C. The conditional welfare function for each economy is represented by

$$V_0^B = E_0 \sum_{t=0}^{\infty} \beta^t U(c_t^B, h_t^B), \quad (19)$$

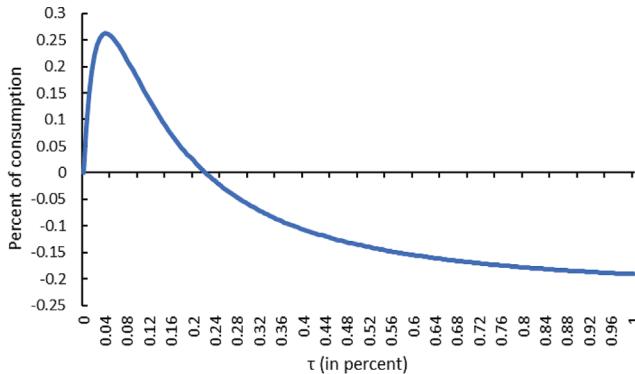

and

$$V_0^C = E_0 \sum_{t=0}^{\infty} \beta^t U(c_t^C, h_t^C), \quad (20)$$

where c_t^i and h_t^i represent the contingent plans for consumption and hours under economy i , with $i = B, C$. Let Ψ^{lbd} denote the fraction of economy C’s consumption required in order for households in economy B to have the same welfare levels as households in economy C. Therefore, welfare is redefined as

$$V_0^C = E_0 \sum_{t=0}^{\infty} \beta^t U((1 + \Psi^{lbd}) c_t^B, h_t^B).$$

Figure 14. Optimality of CFMs in an Economy with a Learning-by-Doing Externality

Note: This figure shows welfare gains from CFMs in terms of the fraction of consumption required for households under a regime with no CFMs to be as well off as households under a regime with CFMs. The horizontal axis measures the intensity of CFMs through the parameter τ . The vertical axis measures the welfare benefit (in terms of consumption) of different degrees of CFMs.

Given the functional form of utility represented in Equation (5), Ψ^{lbd} can be written as

$$\Psi^{lbd} = \left\{ 1 - \left[\frac{(1-\gamma)V_0^B + (1-\theta_t)^{-1}}{(1-\gamma)V_0^C + (1-\theta_t)^{-1}} \right]^{\frac{1}{\omega(1-\gamma)}} \right\}. \quad (21)$$

The welfare gain is computed through a second-order approximation of Equation (21). Figure 14 shows the welfare gain described in Equation (21) under different values of τ . Welfare is an increasing function in the level of CFMs up to $\tau = 0.045$, meaning that 0.25 percent of household consumption should be transferred to a regime with no capital controls in order for households in that regime to have the same expected level of utility as households in a regime with capital controls in place.

As shown in the previous subsection, CFMs are effective in discouraging households from financing tradable consumption with foreign borrowing, therefore limiting costly resource reallocation from the tradable to the non-tradable sector, and thus increase agents' welfare. That is, when there is an LBD externality in this economy,

limiting foreign borrowing can be considered close to a second-best policy.²¹ However, it is clear that the use of CFMs should be handled with care, as the benefits from CFMs dissipate relatively quickly, even for relatively low values of τ . Results show that there are benefits from households having access to international capital markets, and some reallocation from the tradable to non-tradable sector is indeed the efficient response to capital inflow surges. All these issues highlight the implementation challenges of CFMs.

3.8 Sensitivity Analysis

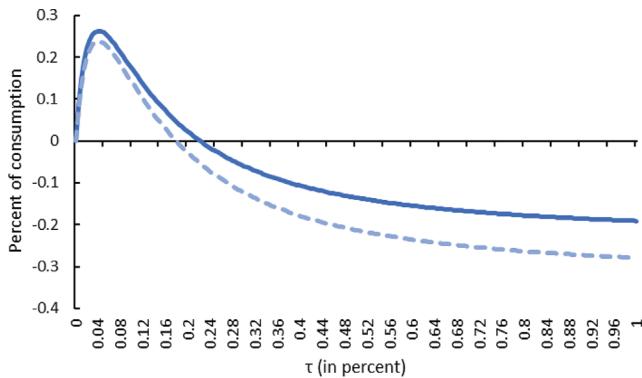

While most of the parameters used in this paper come directly from a large and standard strand of literature on small open economy models, they can be easily estimated from observable data. However, the parameters for the LBD mechanism are hard to estimate for EMDEs due to data constraints.

Against this backdrop, this subsection analyzes the sensitivity of the results to the share of organizational capital in the production function of tradables, the learning rate parameter ξ . This parameter is obtained from Cooper and Johri (2002), who estimate these parameters for U.S. manufacturing sector firms, and corresponds to the identification scheme of assuming that the production function exhibits constant returns to scale. As a robustness the importance of organizational capital in the tradable sector (ξ) is reduced from 0.26 to 0.08. This value is the lowest level of ξ that allows the analysis to maintain the assumption regarding constant returns to scale of production at the firm level and increasing returns to scale at the aggregate level (i.e., $\alpha + (1 - \alpha) + \xi > 1$).

Figure 15 shows the welfare benefit under the lower learning rate in the tradable sector (solid line). Even though the welfare benefit of CFMs is smaller as the benchmark specification, still the use of CFMs is welfare improving. A lower learning rate does not have a material effect on the model dynamics to global interest rate shocks. Nevertheless, the LBD mechanism is likely to be larger in EMDEs

²¹As discussed in the previous section, the optimality of limiting foreign borrowing does not depend on the direction of the shock to the global interest rate.

Figure 15. Optimality of CFMs Under Different Levels of a Learning-by-Doing Externality

Note: This figure shows welfare gains from CFMs in terms of the fraction of consumption required for households under a regime with no CFMs to be as well off as households under a regime with CFMs. The horizontal axis measures the intensity of CFMs through the parameter τ . The vertical axis measures the welfare benefit (in terms of consumption) of different degrees of CFMs. The solid line uses the baseline level of organizational capital (0.26) and the dashed line uses a lower level of organizational capital (0.08).

(as compared with the United States), as the share of manufacturing in the exportable sector is significantly larger in some of these economies.²² In this regard, the welfare gain from CFMs could be larger in some EMDEs, with the results presented in this paper representing a lower bound of the welfare benefit of CFMs in the presence of Dutch disease.

4. Conclusion

This paper documented that accommodative monetary policy in the United States in the post-GFC period coincided with textbook Dutch disease symptoms in EMDEs: real currency appreciation and a contraction in tradable output. The paper also shows evidence

²²For example García-Cicco and Kawamura (2015), in a model calibrated to Chilean data, show that the level of organizational capital is much larger than the levels estimated by Cooper and Johri (2002) and commonly used in the literature.

consistent with CFMs effectively insulating EMDEs from U.S. monetary policy shocks. In order to evaluate the welfare implications of this policy intervention, the paper develops a DSGE small open economy model that exhibits an LBD externality in the tradable sector. The LBD externality calls for the use of CFMs on inflows to limit costly resource misallocation and to bring tradable production close to the efficient level. In this regard the use of CFMs to address Dutch disease effects would be most suitable for EMDEs with a sizable manufacturing export sector, a sector identified in the literature as the one in which LBD accrues the most.

Using parameters commonly used in the Dutch disease literature, the paper finds that the use of CFMs could be a second-best policy if agents fail to internalize the moving cost of shifting resources from the tradable to non-tradable sectors. However, model simulations suggest that the use of CFMs should be handled with care, as capital inflows do lead to some resource allocation efficiency gains and the benefits of CFMs accrue mainly at relatively low levels of restrictions. Also, the fact that the LBD externality is not observable and difficult to measure, calibrating CFMs (not only regarding their magnitude but also their duration) could be a challenging endeavor for policymakers. Importantly, the use of CFMs should not be a substitute for necessary macro adjustment to correct underlying imbalances, although CFMs appear as a sensible policy alternative that can provide policymakers some breathing space when the scope for foreign exchange intervention or monetary policy adjustment is limited.

This paper presents an analytical framework with a novel mechanism to think about the merits of CFMs in the presence of LBD externalities. By doing so, it puts forward a rationale for why CFMs can be a useful part of the toolkit to manage the consequences of capital flows. It has done so through a parsimonious model, but future research should consider also the interactions of LBD with other externalities as well as the role of other policies in an integrated fashion. At the same time, in a context of rising global interest rates amid the normalization in monetary policy by the major central banks, the model could be extended in order to analyze the merits of capital account liberalization in order to prevent a sharp currency depreciation and an inefficient reallocation from the non-tradable to the tradable sector.
